Abstract. Methane (CH4) is a potent greenhouse gas and plays a significant role in recent increasing global temperatures. The oceans are a natural source of methane contributing to atmospheric methane concentrations, yet our understanding of the oceanic methane cycle is poorly constrained. Accumulating evidence indicates that a significant part of oceanic CH4 is produced in oxygenated surface waters as a by-product of phytoplanktonic activity. This study focused on the subtropical North Atlantic Ocean (26°N, 80°W and 26°N, 18°W) where the distribution of dissolved CH4 concentrations and associated air–sea fluxes during winter 2020 were investigated. Water samples from 64 stations were collected from the upper water column up to depths of 400 m. The upper oxic mixed layer was oversaturated in dissolved CH4 with concentrations ranging 3–7 nmol L−1, with the highest concentrations of 7–10 nmol L−1 found to the east of the transect, consistent with other subtropical regions of the world’s oceans. The high anomalies of dissolved CH4 were found to be associated with phosphate-depleted waters and regions where the abundance of the ubiquitous picocyanobacteria Synechococcus and Prochlorococcus were elevated. Although other phytoplanktonic phyla cannot be excluded, this suggests that cyanobacteria contribute to the release of CH4 in this region. The calculation of air–sea fluxes further confirmed the subtropical North Atlantic Ocean as a source of CH4. This study provides evidence to corroborate the key role that picocyanobacteria play in helping to explain the oversaturation of CH4 found in surface mixed layer of the open ocean, otherwise known as the “ocean methane paradox”.

1 Introduction

Since the industrial revolution, the average global temperature has increased at the fastest rate in recorded history, primarily driven by growing emissions of greenhouse gases (GHGs). Among them, methane (CH4) is considered the second-largest contributor to Earth warming after carbon dioxide (CO2), with an atmospheric concentration of 1866 ppb (IPCC, 2021). Over the last 50 years, CH4 concentrations have increased by 20 % (Karl et al., 2008; Rhee et al., 2009) – and are expected to rise further by approximately 2 % yr−1 (Dang and Li, 2018).

Oceans were generally considered to be a minor contributor to the total global CH4 budget, yet recent calculations indicate that oceans could emit 6 to 17 Tg CH4 yr−1, i.e., 1 % to 10 % of the total natural emissions (Weber et al., 2019). This large variability reflects the great uncertainty in the contribution of natural sources due to a lack of data and understanding of the sources and controls of oceanic CH4 emissions.

The marine flux of CH4 results from the balance between production and oxidation processes; for instance, the microbial anaerobic oxidation of CH4 (AOM) in sediments sig-
nificantly decreases CH$_4$ fluxes to the atmosphere, thus representing an important carbon sink in the ocean (Oppo et al., 2020). In fact, the marine methane release is dominated by shallow coastal environments including estuaries (up to 75 %; Weber et al., 2019). In marine sediments CH$_4$ can be released via microbial anaerobic methanogenesis as a consequence of the degradation of organic matter; it accumulates in the sediment, eventually forming gas hydrates, which may then be released into the overlying water column. Under the influence of pressure and temperature CH$_4$ diffuses out of the sediment and ebullition carries CH$_4$ to the atmosphere (Weber et al., 2019).

In open oxygenated waters, the primary mechanism controlling the CH$_4$ emissions is aerobic methanotrophy that converts CH$_4$ into CO$_2$ (Weber et al., 2019). However, this process could be overcome by in situ production of CH$_4$ in upper oxic waters that can significantly contribute to marine CH$_4$ fluxes to the atmosphere. Typical CH$_4$ depth distribution in the open ocean indicates a general oversaturation in the mixed layer (Reeburgh, 2007). In the surface waters of the Pacific Ocean (Weller et al., 2013), the Indian Ocean (Bui et al., 2018) and the Atlantic Ocean, values of 2–5 nmol L$^{-1}$ and a maximum of 10 nmol L$^{-1}$ were measured near the surface (Scranton and Brewer, 1977). These observations make the global ocean a net source of CH$_4$ to the atmosphere with a weighted supersaturation of 120 % (Kock and Bange, 2007). Exemptions are the Southern Ocean and the central Arctic Ocean, where surface waters are undersaturated in CH$_4$, either due to extensive upwelling supplying CH$_4$-depleted water to the surface (Bui et al., 2018) or the limitation of air–sea exchanges by ice cover (Weber et al., 2019).

The oversaturation of the surface mixed layer, commonly known as the “ocean methane paradox” (OMP), was explained by the result of methanogenic activity from Archaea living within anaerobic cavities of zooplankton guts and anaerobic micro-environments inside sinking particles of organic matter (Reeburgh, 2007). Initially, only microbes from the Archaea domain were thought to have the capability of producing CH$_4$ under strict anaerobic conditions. Although one cannot exclude this process to explain the methane paradox (Schmale et al., 2018) (Stawiarski et al., 2019), an increasing number of studies have revealed relationships between CH$_4$ anomalies in surface waters and the presence of certain phytoplanktonic groups such as coccolithophores (Lenhart et al., 2016a) and cyanobacteria (Bižić et al., 2020)

Cyanobacteria are ubiquitous to every aqueous environment on Earth in both illuminated and dark water bodies (Percival, 2014). In the open ocean, small-sized picophytoplankton of the genera Prochlorococcus spp. and Synechococcus spp. account for $\sim$ 80 % of the total phytoplanktonic chlorophyll $a$ (Hickman et al., 2010) and could represent up to 8.5 % and 16.7 % of the ocean net primary production (ONPP), respectively (Flombaum et al., 2013). Generally, nutrient limitation sets the upper limit for primary production and the distribution of Prochlorococcus and Syne-
ters of the subtropical North Atlantic Ocean as part of the JC191 hydrographical cruise (RRS James Cook, January–March 2020). Furthermore, we present data on the distribution of the two dominant cyanobacteria, Prochlorococcus and Synechococcus, to highlight the contribution of the planktonic community to the CH4 flux. More specifically, our objectives were to confirm the presence of CH4 anomalies in surface waters and the associated air–sea fluxes, as well as to propose possible mechanisms and sources controlling the CH4 distribution by examining the relationships between physicochemical and biological parameters.

2 Methods

2.1 Water sampling and analysis for dissolved gas concentrations

Seawater samples were collected during the JC191 hydrographical cruise (as part of the GO-SHIP program, PI A. Sanchez-Franks; Sanchez-Franks, 2020) on board the RRS James Cook between January and March 2020 along a west–east transect in the subtropical North Atlantic from Fort Lauderdale (Florida), USA, to Santa Cruz de Tenerife, Spain, on the nominal 24°N parallel. 64 profiles (out of 135 stations occupied by CTD – conductivity, temperature, depth – casts in total) from the surface to 400 m depth (or full depth for the shallower continental margin stations) were sampled (Fig. 1).

Water samples for dissolved CH4 measurements were collected into 20 mL headspace vials using a 24-Niskin-bottle rosette equipped with a SBE911+ CTD, an AquaTracka III fluorometer (Chelsea Technologies) and a dissolved oxygen sensor (Sea-Bird SBE 43). Dissolved gas samples were poisoned with Hg(Cl)2, then fitted with Teflon stopcocks and crimp-sealed under exclusion of any air bubbles. Samples were immediately stored at 4 °C until transferred to a 1 mL injection loop, maintained at 150 °C and injected into a 50 °C heated column. Calibrations were made by injecting a known volume of standard gas (Messer® 1000, 500 and 100 ppm ± 1 ppm CH4 in helium and 500 ppb H2 in helium). All analyses were made in duplicate, and results are given as averaged values. The detection threshold of this method is 0.2 nmol for dissolved CH4, and variation between duplicates was 5%.

2.2 Inorganic nutrient analysis

Samples for inorganic nutrient analysis (NO2−, NO3−, NH4+, PO43−) were collected unfiltered into sterile 15 mL centrifuge tubes (rinsed three times with water from the same Niskin). Samples were analyzed directly from the collection tubes within 1–8 h and measured from the lowest to the highest concentration (surface to deep) to reduce any carryover effects. Nutrients were analyzed on board using a four-channel Seal Analytical AA3 segmented flow autoanalyzer following GO-SHIP protocols (Becker et al., 2020). In order to test the accuracy and precision of the analyses, certified reference materials (CRMs) from KANSO Technos Co. (lots lot CD, CJ, CI and lot BW) were measured in triplicate in every run.

2.3 Cyanobacteria sampling and analysis

38 of the stations occupied during JC191 were sampled at six depths in the upper water column (max. sampling depth 375 m) following the live fluorescence profiles to determine the prevailing community of primary producers (unpublished data, Marx 2020). Bulk water samples (5 L) were collected from Niskin bottles, from which subsamples for the flow cytometric determination of Prochlorococcus and Synechococcus abundances were collected. 4 mL of sample water was immediately fixed with 40 mL glutaraldehyde solution (50 %) and stored at 4 °C until transferred to a low-temperature freezer (−80 °C) after 12 h. Samples were analyzed at the University of Portsmouth on a CyFlow Cube 8 (Sysmex) flow cytometer immediately after defrosting and at a flow rate of 1 µL s−1. The distinction between Prochlorococcus and Synechococcus was achieved by gating each group according to its fluorescence signals (red and orange fluorescence) against the size fractionation (forward and side scatter). For each of the stations sampled, the mixed layer depth (MLD, defined as the depth at which temperature decreased by 1 °C from the surface) was determined, and the integrated average in abundance above said MLD was calculated.

2.4 Statistical analyses

In order to determine the biological and physicochemical parameters that influence the distribution of dissolved methane

Figure 1. Cruise track of the JC191 24N expedition from Fort Lauderdale (Florida), USA, to Santa Cruz de Tenerife, Spain (January–March 2020). White numbers indicate some of the total 135 CTD stations.
in surface waters, a principal component analysis (PCA) was applied. This statistical tool simplifies the underlying structure of the multivariate dataset by converting a large number of variables into a smaller number of variables, i.e., components (PCs), with a minimum loss of information. Each PC is associated with an eigenvalue that indicates the variation in the data. Here, the PCA computes a singular value decomposition of the data matrix and does not incorporate the eigenvalue of the covariance matrix to maintain numerical accuracy. Then, factor loadings were calculated, with a high factor loading indicating a significant correlation between variables. Additionally, Kendall rank correlations were computed to evaluate associations between two variables (e.g., methane concentrations and fluorescence or phytoplankton abundances). All statistics were performed with RStudio and the R “stats package” (R Core Team, 2013).

2.5 Flux calculation

The flux of air–sea CH4 was calculated following established methods (Kelley and Jeffrey, 2002; Wanninkhof, 2014):

\[ F = k(C_w - C_a), \]

where \( F \) is the CH4 flux (mol m\(^{-2}\) d\(^{-1}\)) from seawater to air, with \( k \) as a gas transfer coefficient under consideration of wind speed, \( C_w \) as the average CH4 concentration measured in surface water and \( C_a \) as the equilibrated seawater–air CH4 concentration. Wind speed data were obtained from on-ship measurements throughout the cruise transect, and the concentration of CH4 in the air was assumed to be 1.9 ppm (based on NOAA, Global Monitoring Laboratory https://gml.noaa.gov/ccgg/trends_ch4/, last access: 28 August 2022). The gas transfer coefficient \( k \) was calculated following

\[ k = 0.251 <U^2> (Sc/660)^{-0.05}, \]

where \( <U^2> \) represents the average neutral stability of winds at 10 m height squared, and \( Sc \) indicates the Schmidt number, taking into account the kinematic viscosity of water and the molecular diffusion coefficient of the gas. From inverse modeling using CCMP winds and the Modular Ocean Model–General Circulation Model (MOM3 GCM), a value of 0.251 was obtained. \( Sc \) was calculated as

\[ Sc = A + Bt + Ct^2 + dt^3 + Et^4, \]

with coefficients \( A, B, C, D \) and \( E \) obtained from a least square fourth-order polynomial fit (Wanninkhof, 2014).

3 Results

3.1 Spatial distribution of physicochemical parameters

CH4 concentrations in surface waters of the subtropical North Atlantic along the 24°N transect were distributed nonuniformly between 3 and 10 nmol L\(^{-1}\), i.e., systematically above saturation of ~2.7 nmol L\(^{-1}\). The lowest concentrations of CH4 of 3–4 nmol L\(^{-1}\) were found in the central gyre system above the mid-Atlantic ridge (~45°W), with increasing values of 8–10 nmol L\(^{-1}\) in both western and eastern boundaries closer to the continental shelf (Fig. 2a).

Chlorophyll \( a \) (Chl \( a \), Fig. 2b) from real-time fluorescence profiles exhibits the highest concentrations near both the western and eastern shore systems and the lowest concentrations in surface waters throughout the central gyre system (~0.1 µg L\(^{-1}\), Fig. 2). A deep chlorophyll maximum (DCM) was observed between 100 and 130 m water depth and was consistently above the mixed layer depth (MLD). Concentrations of Chl \( a \) increase towards the Mauritanian upwelling off the North African coast to above 0.4 µg L\(^{-1}\), indicating higher primary production due to enhanced nutrient supply. Accordingly, light transmission is decreased due to higher content of suspended particles in the water column (Fig. 2h). Furthermore, fluorescence aligns with patterns of dissolved oxygen in the water column of this transect. The surface waters in the subtropical North Atlantic are well oxygenated with concentrations above 200 µmol kg\(^{-1}\) in the top 100 m of the water column, subsequently decreasing with depth. Increased concentrations of dissolved oxygen are observed towards the eastern boundary following enhanced lateral transport from the coastal upwelling (Fig. 2e).

Nitrate and phosphate concentrations were low (~0.1, <0.01 µmol kg\(^{-1}\), respectively) in surface waters throughout the transect with nutriclines >200 m depth, shallowing (~150 m in eastern basin and <100 m in eastern boundary) towards the eastern boundary due to coastal upwelling off the eastern North African coast and associated enhanced mixing of deep, nutrient-enriched waters into surface waters (Fig. 2c and d).

3.2 Sea-to-air methane flux

At most stations, air–sea CH4 flux was 1–2 µmol m\(^{-2}\) d\(^{-1}\), with maximum values of 5 µmol m\(^{-2}\) d\(^{-1}\) in the area of 24°N 25°W (Fig. 3). Only one station (~40°W) had a negative CH4 flux, which indicates a sink of CH4. The overall average flux across the subtropical North Atlantic was 1.9 µmol m\(^{-2}\) d\(^{-1}\). However, it should be noted that the air–sea flux of CH4 is dependent on the wind speed and can be locally different, varying depending on specific weather conditions.

Although the sea-to-air flux of CH4 presented here broadly agrees with similar values of 1.6 µmol m\(^{-2}\) d\(^{-1}\) measured in the oligotrophic North Pacific, it can differ substantially both temporarily and spatially. For instance, the sea-to-air flux of CH4 in the Sargasso Sea, also partly encompassed in the transect of JC191, fluctuates between 1.6 and 4.4 µmol m\(^{-2}\) d\(^{-1}\) depending on the season and weather conditions (Holmes et al., 2014). Furthermore, the base ecosystem can impact the sea-to-air flux of CH4 if compared to
Figure 2. Distribution of (a) CH$_4$, (b) Chl a, (c) NO$_3$, (d) PO$_4$, (e) dissolved oxygen, (f) salinity, (g) temperature and (h) transmission along the cruise track. Chl a, dissolved oxygen, salinity, temperature and transmission data originate from sensors attached to the CTD. CH$_4$, NO$_3$, and PO$_4$ were measured analytically. Some of the data were taken from CCHDO (Sanchez-Franks, 2020).

Figure 3. Sea-to-air CH$_4$ flux (µmol m$^{-2}$ d$^{-1}$) along the cruise track of JC191. Dots indicate stations occupied by CTD casts.

other oceanic regions such as Belgian coastal zones with 1–160 µmol CH$_4$ m$^{-2}$ d$^{-1}$ (Borges et al., 2016), Red Sea mangroves with 13.3 µmol CH$_4$ m$^{-2}$ d$^{-1}$ (Sea et al., 2018), or surveys in the East China Sea (6.5–7.4 µmol m$^{-2}$ d$^{-1}$, Ye et al., 2015) and the Gulf of Mexico (0.38 µmol m$^{-2}$ d$^{-1}$, Kelley and Jeffrey, 2002).

4 Discussion

4.1 Methane distribution in surface waters of the subtropical North Atlantic Ocean

Our data across the subtropical North Atlantic Ocean unambiguously indicate an oversaturation in CH$_4$ of the surface layer (400 m) of 110 % to 370 %, which is in agreement with previous observations describing concentrations varying between 2 and 5 nmol L$^{-1}$ and maximum values of 10 nmol L$^{-1}$ (Scranton and Brewer, 1977; Conrad and Seiler, 1988; Forster et al., 2009; de la Paz et al., 2015; Leonte et al., 2020). This is also in line with previous observations describing the upper layer in subtropical areas of the global ocean as a source of CH$_4$ to the atmosphere (Reeburgh, 2007; Dang and Li, 2018) and also in some regions of the Arctic Ocean (Kitidis et al., 2010; Kudo et al., 2018). To date, only the Southern Ocean is undersaturated in CH$_4$, although this
is limited by the scarcity of data collected, highlighting the need for increased surveying to be complemented (Bui et al., 2018).

The distribution of dissolved CH₄ was variable across the subtropical North Atlantic, with higher concentrations in the eastern basin (65–80° W) and the western basin (15–30° W) and the lowest concentrations measured in the central gyre system of the transect (30–65° W) (Fig. 2). The vertical distribution of CH₄ appears to be associated with fluorescence; the highest concentrations of CH₄ were found at ~100 m depth, where fluorescence and dissolved oxygen are highest and nutrients levels lowest, which is in agreement with previous findings (Kudo et al., 2018).

PCA was applied to the datasets collected to identify which environmental parameters (nutrients, fluorescence, dissolved oxygen, temperature, salinity, depth, transmission) are related to or influence the distribution of CH₄ along the transect. 54% of the variability could be explained by the first component, which is primarily controlled by depth (Fig. 4). CH₄ is mainly associated with oxygenated surface waters, characterized by low concentrations of nutrients and a higher fluorescence. However, the weak contribution of CH₄ to the first two components may be due to the heterogeneity of its distribution. To fully understand the relationship between the different parameters controlling the distribution of CH₄, we therefore separated the transect into three main regions, i.e., (i) the western basin, (ii) the central gyre system and (iii) the eastern basin. The PCA applied to the regionalized dataset (Fig. 5) revealed that CH₄ is clearly associated with the abundance of primary producers in surface waters (<100 m) in the western basin, while in the central gyre and eastern basin CH₄ concentrations were also influenced either by in situ physical processes such as mixing or mesoscale eddies (Kudo et al., 2018) or by external inputs such as the Mauritanian upwelling that supplies CH₄-enriched waters to the upper layer (Conrad and Seiler, 1988).

Although CH₄ appeared to have a uniform vertical distribution (Fig. 2), selected profiles of CH₄, Chl a, phosphate and dissolved oxygen from two areas of interest, CTD 50 (69.5° W, 24.9° N) and CTD 122 (20.8° W, 25.45° N), showed that the highest concentration of CH₄ in fact corresponds to the maxima of Chl a and dissolved oxygen and the lowest concentrations of phosphate (Fig. 6). The correlation between CH₄ and Chl a (Kendall rank correlation test, \( r^2 = p < 0.05 \)) further suggests that the primary producers play a role in the production of CH₄.

At station 50, the relationship between CH₄, Chl a and phosphate appears to be linear, e.g., CH₄ concentration decreasing as Chl a decreases and phosphate increases, while at station 122 the CH₄ concentration showed a nonlinear pattern. It is not clear why CH₄ concentrations are variable, but zooplankton grazing could potentially have a substantial impact (Simon et al., 2012). A possible influence of gas seeps on the CH₄ concentration is negligible as gas seeps only influence CH₄ concentrations in the immediate water column above the seeps (Leonte et al., 2020). Below 250 m water depth, CH₄ concentrations decrease, corresponding to an increase in phosphate and minimal Chl a concentrations, again suggesting the influence of primary producers (Brown et al., 2014).

### 4.2 Methane production linked to primary production

Autotrophic cyanobacteria Prochlorococcus and Synechococcus represent a major constituent of primary production in the subtropical North Atlantic; their distribution, however, differs greatly (Flombaum et al., 2013). Whereas Synechococcus solely occupies surface waters up to depths of ~100 m, Prochlorococcus occupies the whole water column, with deep-water maxima just above MLD, and are therefore responsible for fluorescence maxima at 100 to 130 m. The longitudinal distribution also differs between the two taxa: the distribution of Synechococcus is limited to coastal, nutrient-richer waters (Fig. 7), whereas Prochloro-
Figure 5. Principal component analysis of the regionalized dataset: west (80–65° W), central (65–30° W) and east (30–20° W). Numbers on the x and y axes indicate the factor loadings of each variable of each principal component (PC). The percentages show the explained variability in the dataset by each PC. CH$_4$ is highlighted in red.

Figure 6. Selected data from CTD 50 (69.5° W, 24.9° N) and CTD 122 (20.8° W, 25.45° N) for CH$_4$ (red circles), Chl a (green triangles), phosphate (purple squares) and dissolved oxygen (orange).

Figure 7. Depth-integrated abundance of Synechococcus (in $10^3$ cells mL$^{-1}$) above MLD. Black dots represent the 38 out of the total 135 stations sampled for cyanobacterial abundance.

coccus dominates the community throughout the transect (Fig. 8). CH$_4$ distribution across the subtropical North Atlantic suggests that the influence of the cyanobacterial community is present; the highest CH$_4$ concentrations were found (1) at DCM in the central gyre system, where Prochlorococcus is the predominant genus, and (2) at the gyre boundaries, where higher abundances of both Prochlorococcus and Synechococcus were found. A PCA applied to the dataset including abundances of both cyanobacteria strengthens the conclusion that

https://doi.org/10.5194/os-18-1377-2022
CH$_4$ production appears to be associated with primary production (Fig. 9).

The bordering Gulf Stream to the west and the Canary Stream to the east provide a resupply of nutrients (Williams et al., 2011) and therefore support a greater abundance of cyanobacteria; the Canary Stream also presents a pathway for the horizontal transfer of organic matter from the North African coast to the open ocean. Previous studies confirm high OM production in the eastern subtropical North Atlantic as a result of the high rates of primary production fueled by the Mauritanian upwelling (Reynolds et al., 2014). The transmission data (Fig. 2h) suggest the export of organic matter throughout the eastern basin, which could contain MPn and thus a potential source of CH$_4$. Elevated CH$_4$ concentrations are mainly limited to the highly productive boundary systems, whilst the central gyre, which lacks a sufficient resupply of bioavailable nutrients due to its downwelling nature, results in a decreased abundance of both Prochlorococcus and Synechococcus and hence decreased CH$_4$ concentrations (Fig. 2a). In this especially P-limited region, alternative nutrient sources such as the degradation of DOM to access organic phosphorus compounds become increasingly important in order for the cyanobacteria to meet their nutrient needs. The degradation of dissolved organic phosphorus via alkaline phosphatases (AP) such as phoA or phoX and the overexpression of the phosphate binding protein (pstS) have been believed to be the main adaptations to P stress (Luo et al., 2009; Cox and Saito, 2013; Sebastian and Ammerman, 2009). Recently, however, evidence was brought forth that some strains of Prochlorococcus can also oxidize MPn and other higher phosphonate compounds while releasing formate and potentially CH$_4$ as a by-product (Sosa et al., 2019a). Phosphonates are notably abundant and enriched in DOM (Sosa et al., 2019b), and their degradation releases considerable amounts of CH$_4$. Prochlorococcus and Synechococcus are the most abundant primary producers in the oligotrophic ocean and as such produce considerable amounts of semi-labile DOM; both can synthesize phosphoenolpyruvate mutases (pepM), and therefore the DOM produced carries an enriched pool of MPn (Repeta et al., 2016; Sosa et al., 2019a). However, the metabolism of MPn is heavily regulated by bioavailable phosphate, and thus the metabolic pathway of pepM might be heavily downregulated in the subtropical North Atlantic, whereas under replete conditions, i.e., in the North Pacific, Prochlorococcus can allocate up to 40% of its internal P quota to phosphonate synthesis (Acker et al., 2022). Yet, the trait to produce phosphonates is located on genomic islands, is subject to horizontal gene transfer and can be frequently exchanged among marine microbial communities. Hence, proteobacteria such Pelagibacter spp. in the SAR11 clade also obtain pepM and are able to produce phosphonates (Acker et al., 2022). Similarly, the trait of phosphonate consumption is subject to horizontal gene transfer, and high-light strains of Prochlorococcus carry both production and consumption traits. They can therefore also utilize MPn as an alternative P source (Acker et al., 2022). The demethylation of MPn is mostly attributed as occurring under P-limiting conditions, such as in oligotrophic oceanic regions. Further, most MPn oxidation and subsequent release of CH$_4$ are due to bacterial degradation of DOM and the breakdown of highly energetic carbon–phosphorus bonds via C–P lyases, which are encoded by the phn operon, with transport systems including phnC, phnD, phnE and phnJ responsible for the cleavage of the C–P bond (Sosa et al., 2020). C–P lyases are abundant among Pelagibacter spp. and other alpha and gamma proteobacteria and can be found in ~50% of organisms in the North Atlantic, where DOP concentrations are 4-fold lower with respect to the North Pacific (Sosa et al., 2020). Carini et al. (2014) estimated a potential production of 0.01–0.05 nM CH$_4$ d$^{-1}$ by Pelagibacterales via C–P cleavage within the MPn pathway (Carini et al., 2014). However, due to complex biogeochemical and physical processes involved, in situ production of CH$_4$ is difficult to assess, and quantifying the individual contribution of primary producers to CH$_4$ production was not the primary scope of the work presented. Here, the focus was to link the distribution of CH$_4$ in the subtropical North Atlantic to two vastly abundant cyanobacteria as exemplary primary producers, Prochlorococcus and Synechococcus, in order to draw conclusions which might explain the ocean methane paradox. Many mechanisms and precursors of oceanic in situ production of CH$_4$ remain unknown, and it is unclear whether cyanobacteria such as Prochlorococcus or Synechococcus are responsible for the release of CH$_4$, mainly via the degradation of MPn or indirectly by producing semi-labile DOM containing MPn cleaved by the bacterial community. Furthermore, recent laboratory-based studies also confirmed that planktonic organisms produce CH$_4$ per se under high light intensities; Prochlorococcus showed higher potential in CH$_4$ production than Synechococcus, with 0.8–110 and 0.01–0.6 pmol CH$_4$ per 10$^8$ cells per hour, respectively. Larger cyanobacteria such as Microcystis spp. ex-

Figure 9. Principal component analysis (PCA) between dissolved CH$_4$ concentrations (red), Prochlorococcus and Synechococcus abundances (light blue), and other physicochemical parameters (nutrients, depth, fluorescence, temperature, salinity and turbidity). Numbers on the x and y axes indicate the factor loadings of each variable of each principal component (PC). The percentages show the explained variability in the dataset by each PC.

ceeded this by up to $0.51 \pm 0.26 \mu\text{mol g}^{-1} \text{h}^{-1}$ (Bižić et al., 2020).

Nonetheless, Prochlorococcus alone produces $\sim 22 \text{nM CH}_4 \text{d}^{-1}$ and therefore substantially contributes to the supersaturation of oligotrophic oceanic regions (typically between 7 and 25 nM) as well as to the oversaturated state measured here (up to 10 nM) in the subtropical North Atlantic (Bižić et al., 2020). Cyanobacteria can greatly influence and potentially control CH$_4$ production in the marine environment, although other marine organisms such as different bacterial clades or coccolithophores are believed to also contribute to overall CH$_4$ production. Nitrogen-fixing diazotrophs such as Trichodesmium spp. or Rhodopseudomonas palustris may contribute to an even higher degree (Bižić-Ionescu et al., 2018; Zheng et al., 2018), and, although spatially limited with Trichodesmium spp. dominating the western basin and Hemilaulus associated Richelia symbionts more so in the eastern basin (Luo et al., 2009), they are also abundant throughout the subtropical North Atlantic. Trichodesmium has higher nutrient requirements and can therefore outcompete cyanobacteria in uptake of inorganic nutrients and degradation of alternative sources; yet, energy-intensive diazotrophic nitrogen fixation is controlled by micronutrients such as iron (Macovei et al., 2019) and primarily occurs in the western basin, an area of high iron input by aeolian plumes originating from the Saharan desert (Ratten et al., 2015; Reynolds et al., 2014). Lastly, coccolithophores such as the ubiquitously abundant Emiliania huxleyi can also produce CH$_4$ (between 0.7 and $3.1 \pm 0.4 \text{CH}_4$ per gram POC per day; Lenhart et al., 2016b) from OM degradation and are believed to increase in abundance in the subtropical North Atlantic with increasing CO$_2$ concentrations at the air–sea interface due to further anthropogenic perturbation of the atmospheric CO$_2$ budget (Krumhardt et al., 2015).

Nonetheless, the data presented here suggest that the cyanobacterial community most likely plays a significant key role in the CH$_4$ flux in surface waters and the degradation of MPn from semi-labile DOM, helping to explain the methane paradox and hence the air–sea flux of CH$_4$ (Sosa et al., 2019a). Further investigation needs to focus on gathering in situ data and should also include future scenarios, considering future climate and whole-ecosystem community responses to consequences of altered climate conditions. The base ecosystem, specifically in P-limited regions, is ever changing, and highly adapted and horizontal transfer of genomic traits of P acquisition via various genomic pathways might become inherently important. Further work should also be considered in regards to mesocosm incubation studies with in situ communities of natural composition to improve our understanding of the various processes and interactions involved in oceanic CH$_4$ production linked to primary producers to explain the ocean methane paradox.

5 Conclusions

Our study demonstrates that the subtropical North Atlantic Ocean does indeed act as a source of CH$_4$ to the atmosphere, most likely controlled by cyanobacteria, which are the dominant primary producers in the surface waters. Yet, anomalies found at depths below 200 m could also be attributed to the degradation of sinking organic material. The concentrations of dissolved CH$_4$ in this study were considerably higher near shelf regions and in the eastern boundary under the influence of the Mauritanian upwelling. The accumulation of organic matter and nutrients in these areas provides favorable conditions for both aerobic and anaerobic CH$_4$ production. It is expected that with increasing stratification and subsequent reduction in nutrient supply to the surface oligotrophic North Atlantic Ocean, the prevailing P limitation will be further exacerbated, whereas coastal and shelf regions with increasing anthropogenic inputs of nutrients could experience more
frequent cyanobacterial blooms, which will in turn enhance CH$_4$ production (Dang and Li, 2018).

**Data availability.** All data are available from the authors upon request.

**Author contributions.** AK carried out dissolved gas sample collection, measurements and data analysis and drafted the final paper. LM carried out phytoplanktonic sample collection, measurements and data analysis and supervised biological part of the survey. TC carried out nutrient sample collection, measurements and data analysis. EM carried out nutrient sample collection, measurements and data analysis. CB helped to plan and prepare for the cruise as well as result evaluation and provided overall project supervision. All authors contributed equally to the paper writing and made substantial input to the final version.

**Competing interests.** The contact author has declared that none of the authors has any competing interests.

**Disclaimer.** Publisher’s note: Copernicus Publications remains neutral with regard to jurisdictional claims in published maps and institutional affiliations.

**Acknowledgements.** The authors gratefully acknowledge the PI of the JC191 cruise, Alejandra Sanchez-Franks (National Oceanography Centre, UK), for the great scientific support and for providing cruise data. This work would not have been possible without the support and help of the captain and crew of RRS James Cook. The authors would also like to acknowledge Eric Mace (Station Biologique de Roscoff), the CNRS technician, for his technical support in the preparation of the cruise.

**Financial support.** Ship time was funded by NERC as part of the Climate Linked Atlantic Sector Science (CLASS) research program and as a UK contribution to the Global Ocean Ship-based Hydrographic Investigations Program (GO-SHIP). A. Kolomijeca’s participation in the cruise and dissolved gas analyses was funded by the Region Bretagne SAD “FULMAR” project, the Foundation Air Liquide SMIS-4M project and the CNRS (LEFE Memestra). The participation of Lukas Marx and Sarah Reynolds was funded by the University of Portsmouth PhD bursary scheme and the UK NERC National Capability program CLASS (Climate Linked Atlantic Sector Science) ECR fellowship.

**Review statement.** This paper was edited by Xinping Hu and reviewed by Leonard Ernst and one anonymous referee.
