Abstract

A distinct, subsurface density front along the eastern St. Anna Trough in the northern Kara Sea is inferred from hydrographic observations in 1996 and 2008–2010. Direct velocity measurements show a persistent northward subsurface current ($\sim 20\,\mathrm{cm\,s^{-1}}$) along the St. Anna Trough eastern flank. This sheared flow, carrying the outflow from the Barents and Kara Seas to the Arctic Ocean, is also evident from shipboard observations as well as from geostrophic velocities and numerical model simulations. Although no clear evidence for the occurrence of shear instabilities could be obtained, we speculate that the enhanced vertical mixing along the St. Anna Trough eastern flank promoted by a vertical velocity shear favors the upward heat loss from the intermediate warm Atlantic water layer. The associated upward heat flux is inferred to $50\text{–}100\,\mathrm{W\,m^{-2}}$ using hydrographic data and model simulations. The zone of lowered sea ice thickness and concentration essentially marks the Atlantic water pathway in the St. Anna Trough and adjacent Nansen Basin continental margin from both sea-ice remote sensing observations and model simulations. In fact, the seaice shows a consistently delayed freeze-up onset during fall and a reduction in the seaice thickness during winter. This is consistent with our results on the enhanced Atlantic water heat loss along the Atlantic water pathway in the St. Anna Trough.[1]

1 Introduction

The warm Atlantic water (AW) plays a role in reducing the sea-ice cover in the Northern Hemisphere through upward heat loss (Polyakov et al., 2010). The AW heat loss impacts the ice cover along the Arctic Ocean Eurasian continental margins (Polyakov et al., 2010), but is significantly stronger over the regions of the AW inflow into the Arctic Ocean through the Fram Strait (the Fram Strait branch of AW inflow – FSBW) and in the

---

[1]Dedicated to the memory of our colleague Klaus Hochheim who tragically lost his life in the Arctic expedition in September 2013

Barents Sea (the Barents Sea branch of AW inflow – BSBW). These are areas where the inflowing AW with temperatures $T \sim 5\,°C$ occupies the surface layer directly affecting the ocean–sea ice–atmosphere interface (Sirevaag and Fer, 2009; Årthun et al., 2012; Ivanov et al., 2012). While transiting along the continental slope of Svalbard (red arrows in Fig. 1) and through the Barents Sea (blue arrows in Fig. 1), the AW gradually cools and deepens, getting isolated from the surface. In the area of the St. Anna Trough (hereinafter SAT) in the northern Kara Sea, the submerged BSBW with temperatures slightly above $0\,°C$ merges with a fraction of the warm intermediate FSBW ($T \sim 2.0$–$2.5\,°C$) that enters the western SAT steered by the topography (Hanzlick and Aagaard, 1980; Schauer et al., 2002a) – Figs. 1 and 2. Hereafter we refer to this fraction of the FSBW as SAT-circulating FSBW (SFSBW).

The SFSBW return flow to the Arctic Ocean along the SAT eastern slope is colder and less saline than the FSBW (Schauer et al., 2002b), which indicates mixing and heat loss along the SFSBW pathway in the SAT as suggested by Hanzlick and Aagaard (1980). This allows speculations that a fraction of the SFSBW heat is released upwards with potential implication for the ocean–seaice–atmosphere interface. This paper addresses the issue of SFSBW modification in the SAT with a special focus on water dynamics and mixing occurring along the SAT eastern flank. We suggest that vertical mixing promoted by interaction of the SFSBW with Barents and Kara seas outflow can favor an enhanced AW heat loss that results in a consistent delay of freeze-up onset in fall, seaice thinning in winter, and earlier spring retreat.

2 Data and methods

Oceanographic CTD transects across the SAT (Fig. 2) were taken from the icebreaker *Kapitan Dranitsyn* along $\sim 81°\,N$ (24 October 2008) and along $\sim 81°\,N$ and $82°\,N$ (22–23 August 2009 and 2–3 September 2009, respectively), and from the R/V *Nikolay Evgenov* along $\sim 81°\,N$ (22 September 2010). These sections were sampled using a shipboard SBE19+ CTD (2009–2010), Lockheed Martin Sippican Expendable

Bathythermographs – XBTs and Expendable Conductivity, Temperature, and Depth Profilers – XCTDs (2008). These data were complemented by oceanographic stations occupied across the SAT along $\sim 82°$ N in July 1996 during the ARKXII cruise of the RV *Polarstern* (Schauer et al., 2002b). In addition, we used the velocity data collected from

5 a conventional mooring equipped with Teledyne RD Instruments 300 kHz Workhorse Sentinel Acoustic Doppler Current Profilers (ADCPs) measuring velocity through the depth range of 134–218 m and 376–468 m from 24 August 2009 to 22 September 2010. The mooring was deployed at the eastern slope of the SAT at 81°01′ N, 73°02′ E (Fig. 2) in ~ 520 m water depth.

10 We use gridded satellite data of ice concentration (from the Integrated Climate Data Center at the University of Hamburg, Germany), ice thickness (from the Jet Propulsion Laboratory, USA), and ice drift (from the Center IFREMER of Brest, France). The seaice concentration is derived from the Advanced Microwave Scanning Radiometer for EOS - AMSR-E (2005–2010) and Special Sensor Microwave Imager/Sounder – SS-

15 MIS (2011) (Spreen et al., 2008). The seaice thickness is from the Ice, Cloud, and land Elevation Satellite (ICESat) (Kwok et al., 2009). The sea-ice drift is from the 89 GHz brightness temperature of the AMSR (Ezraty et al., 2007). The spatial grid resolution for ice concentration, thickness and drift is 6.25 km, 25 km and 31.25 km, respectively. The surface level air temperature for the SAT area is from the National Centers for

20 Environmental Prediction (NCEP) reanalysis (Kalnay et al., 1996).

In this study we use ocean velocity, seaice thickness and concentration, and vertical heat fluxes simulated with the coupled ocean–sea ice MIT general circulation model (Marshall et al., 1997). The model has been configured for the Atlantic region north of 30° S including the Nordic Seas and the Arctic Ocean. The model has 50 levels in

25 the vertical, with resolution varying from 10 m in the upper ocean to 550 m in the deep ocean. It was initialized from rest and with the annual mean temperature and salinity from the World Ocean Atlas (WOA) 2005 monthly climatology (Boyer et al., 2005). Bottom topography was interpolated from the ETOPO2 database.

Interactive Discussion

I. A. Dmitrenko et al.

The model was forced at the surface by fluxes of momentum, heat and freshwater computed using bulk formulae and the 1948–2010 6 hourly atmospheric state from the NCEP RA1 reanalysis (Kalnay et al., 1996). At the southern open boundary the model was forced by a 1° resolution global model solution and at Bering Strait a barotropic net inflow of 0.9 Sv was prescribed. The model sea surface salinity was relaxed to the WOA2005 monthly climatology to prevent long-term drifts. In the area of interest, the Barents and Kara Seas including the SAT, the horizontal resolution is 7 km.

The vertical mixing parameterization follows the K-Profile Parameterization (KPP) formulation by Large et al. (1994). Background coefficients of vertical diffusion and viscosity are both $1 \times 10^{-5} \mathrm{m^2\,s^{-1}}$. Biharmonic diffusion and viscosity represent unresolved eddy mixing, both with coefficients of $5 \times 10^{9} \mathrm{m^4\,s^{-1}}$. For further details on the model set-up and application see (Serra et al., 2010).

The model is capable in realistic reproducing of the AW inflow into the Arctic Ocean through the Barents Sea Opening (BSO) and Fram Strait. The vertical structure of temperature and velocity at BSO (Fig. 3a) is in overall agreement with that shown in Skagseth (2008). The AW and the Bear Island Trough outflow temperatures (Fig. 3c) are also consistent with observations. Furthermore, the simulated volume transport of AW (defined as $T > 3\,°C$) of about 1.7 Sv (Figs. 1 and 3e) agrees well with the 1.8 Sv value given in (Skagseth et al., 2008).

In the Fram Strait, the model performs reasonably well in terms of the vertical structure of mean temperature and velocity (Fig. 3b). The West Spitzbergen Current (WSC) has a realistic structure and the temperature of the AW (defined as $T > 2\,°C$ – Fig. 3d) is in agreement with the time series presented in Beszczynska-Moeller et al. (2012). The long-term mean (1997–2009) simulated volume transport of AW in the core of the WSC at Fram Strait of about 1.4 Sv is directly comparable with the 1.3 Sv presented in Beszczynska-Moeller et al. (2012) based on measurements by an array of moorings in Fram Strait over the period 1998–2010 (Figs. 1 and 3f).

The model's ability to adequately simulate the AW dynamics, and thus to elaborate the relationships between the AW dynamics and ice conditions over the SAT region

is briefly discussed elsewhere (Dmitrenko et al., 2012). They also reported on a fair model capability in reproducing the basic hydrography for the downstream area over the Laptev Sea continental margin.

3 Results

First, we focus on the patterns of the CTD profiles taken in 2009, which captured the cross-trough temperature maximums in the intermediate water layer conditioned by the AW inflow into the Arctic Ocean. We suggest that these temperature maximums trace the SFSBW pathway in the SAT (red arrows in Fig. 2). Second, we discuss the density structure across the SAT with a main focus on the eastern flank where the SAT outflow is conditioned by the interaction between the Barents Sea outflow and the SFSBW. Third, we focus on the sheared flow along the SAT eastern slope, revealed from directly measured, inferred (using geostrophy) and simulated velocities.

The 2009 survey shows the SFSBW core temperatures to decrease continuously along the SFSBW pathway from 2.54 °C (st. 85) to 2.35 °C (st. 23) over the SAT western flank, and to 2.20 °C (st. 25) and 2.09 °C (st. 77) over the SAT eastern flank (Figs. 2, 4a and 4b). The same pattern was found by Hanzlick and Aagaard (1980), except that in the 1960s the temperatures were about 1 °C lower. For the SFSBW inflow, the overlaying water layer from 50 to ∼ 100 m exhibits well defined staircases indicating double diffusive upward heat flux from the warm AW layer (Fig. 4a and b). In contrast, the SFSBW outflow shows heavily eroded double diffusive staircases in the upper AW layer. In addition, over the eastern flank of SAT, the halocline and the upper SFSBW (15–80 m) are fresher and less dense relative to the western flank by ∼ 0.3–1.0 psu (Fig. 4a and b), and 0.3–0.7 kg m^{-3}, respectively. At the same time, we observe a deepening of the thermocline and, to a lesser extent, the halocline. All these patterns are in agreement with those revealed by the CTD profiles taken in 1996 (Fig. 4c) and 2008 (not shown; note that no hydrographic information for the western SAT is available for 2010). We also note that in 2009 the intermediate temperature maximum

$(T_{max} = 2.74\,°C)$ in the central part of the SAT mouth at $82°\,N$ (st. 80, Figs. 2 and 4b) exceeds those of the inflowing SFSBW by $0.2–0.4\,°C$.

The observations in 1996 and 2008–2010 consistently show denser water at the eastern flank of the SAT below the halocline layer deeper than $50\,m$ (Fig. 5). In 1996 over the SAT eastern flank shallower than $\sim 300\,m$, the density front extended throughout the water column (Fig. 5a). At $150\,m$, the potential density gradient across the eastern flank along $81°\,N$ ranged from $0.09 \times 10^{-2}\,kg\,m^{-3}\,km^{-1}$ in 2010 (Fig. 5d) to $0.18 \times 10^{-2}\,kg\,m^{-3}\,km^{-1}$ in 2008–2009 (Fig. 5b and c). At $300\,m$, the cross-slope density gradient in 2008–2010 was more uniform with $\sim 0.16–0.18 \times 10^{-2}\,kg\,m^{-3}\,km^{-1}$ (Fig. 5b–d). For comparison, in 1996 the density gradient across the eastern flank was $\sim 0.22 \times 10^{-2}\,kg\,m^{-3}\,km^{-1}$ and $0.09 \times 10^{-2}\,kg\,m^{-3}\,km^{-1}$, at $150\,m$ and $300\,m$, respectively (Fig. 5a). Moreover, in 1996 the surface layer is denser (saltier) and consequently the surface layer stratification is weaker (Fig. 5a).

The mean velocity profile derived from the 2009–2010 yr-long ADCP velocity measurements at the eastern flank shows a relatively stable, nearly barotropic northward flow aligned to $\sim 2°$ in $140–220\,m$ and to $\sim 11°$ in $380–460\,m$, which is consistent with the orientation of the SAT eastern flank. The flow magnitude slightly increases with depth from $17\pm7\,cm\,s^{-1}$ at $140\,m$ (Fig. 6b) to $20 \pm 7\,cm\,s^{-1}$ at $200\,m$, $21 \pm 5\,cm\,s^{-1}$ at $380\,m$, and $23 \pm 5\,cm\,s^{-1}$ at $460\,m$ (not shown). This is in agreement with the shipboard ADCP observations in 1996 showing the northward sub-surface flow of $\sim 25–30\,cm\,s^{-1}$ (Fig. 6b, see Schauer et al., 2002a, for more details). In addition, the velocity profile in Fig. 6b demonstrates a velocity difference of $\sim 20\,cm\,s^{-1}$ in the upper $90\,m$. The sheared flow is also evident from the geostrophic velocity profiles at the mooring position in the SAT eastern flank derived from dynamic heights relative to the 0-dbar pressure surface using the potential density profiles from the nearest CTD stations (Figs. 5 and 6a). The simulated velocities also demonstrate a northward sheared flow along the SAT eastern flank, but twice as large as the geostrophical velocities (Figs. 6c, d, and 7).

Heat loss from the Atlantic water layer

4 Discussion

4.1 Heat loss from the AW in the SAT: causes

Expanding on the AW circulation scheme suggested by Rudels et al. (2004) (Fig. 1), we have demonstrated that a significant portion of the heat associated with the SFSBW in the SAT disappears en route through the SAT. In this context, our observations confirm earlier findings by Hanzlick and Aagaard (1980). This concept, however, requires explanation for the AW intermediate temperature maximum of 2.74 °C observed in the central SAT at 82° N (st. 80) that exceeds the temperature of the SFSBW inflow and outflow by 0.2 °C and 0.65 °C, respectively (Fig. 4a–b).

The current view on the AW circulation in the Eurasian Basin, as proposed by Rudels et al. (2004), implies that the FSBW could potentially feed all three temperature maximums along 82° N. However, the formation of each maximum is due to different FSBW branches. That is, if the SAT on-slope temperature maximums are associated with SFSBW, then the AW temperature maximum in the central SAT could be attributed to the boundary current of the FSBW flowing along the Siberian continental slope (yellow arrows in Fig. 2). The double diffusive staircases noticeable in st. 80 (Fig. 4b) provide evidence for attributing the intermediate temperature maximum of 2.74 °C to the core of the FSBW that follows the Siberian continental slope rather than to the SFSBW. In contrast to the SFSBW inflow (sts. 23 and 85), CTD profiles taken in the SFSBW outflow (sts. 25 and 77) show heavily eroded double diffusive staircases (Fig. 4a and b). The SAT outflow also exhibits strong modification at the upper AW interface that is likely caused by vertical mixing and interaction with cooler and fresher surface water of Barents Sea origin. In contrast, the temperature and salinity profiles in the central SAT (st. 80) are only slightly modified at the upper AW interface and maintain double diffusive staircases that are almost disrupted in sts. 25 and 77 (Fig. 4a and b).

Usually, the enhanced turbulent diffusivity results in substantial degradation of the thermohaline staircases, and the turbulent mixing associated with shear instability nearly disrupts the double-diffusive staircases (e.g., Melling et al., 1984; Dmitrenko

et al., 2008). Over the SAT eastern flank, turbulent mixing between the upper SFSBW and overlaying cooler and fresher Barents and Kara Sea water may be inferred from the velocity shear across the upper SFSBW interface (Figs. 6 and 7). The cross-trough potential density distribution in Fig. 5 is also consistent with a sheared geostrophic flow above the eastern SAT (Fig. 6a). Under this scenario, the SFSBW inflow (double-diffusive staircases present) has not been affected by enhanced turbulent mixing, while the SFSBW outflow (no double-diffusive staircases present) has experienced turbulent mixing during propagation along the eastern SAT. The FSBW boundary current at the central SAT (st. 80) has been partly affected by turbulent mixing, but double-diffusive staircases remain recognizable.

The sheared flow along the eastern SAT in the upper 100 m layer is evident from direct current observations (Fig. 6b), geostrophic velocity calculations (Fig. 6a), and model simulations (Figs. 6c, d and 7). However, the difference between measured and geostrophic velocities indicates that the SFSBW flow along the eastern SAT is not entirely density driven. In this context, Kirillov et al. (2012) recently showed that wind forcing over the northern Kara Sea is important in facilitating the SFSBW outflow from the SAT. The gradient Richardson number (Ri) provides a strong constraint for identifying turbulence produced by shear instability. It is defined as $Ri = N^2 S^{-2}$, where N is the Brunt–Vaisala frequency, and S is the flow vertical shear $S = [(dU/dz)^2 + (dV/dz)^2]^{1/2}$. Turbulent mixing can be assumed to occur for $Ri < 1$ (e.g., Polzin, 1996). Considering a velocity shear $S \sim 0.004 \, s^{-1}$ and the stratification in the 30–90 m layer observed in 1996 (Figs. 5d and 6b) results in $Ri = 3.7$ which significantly exceeds the criterion. Simulations show, however, that velocity shear across the surface layer might reach $0.007 \, s^{-1}$ (Fig. 6d). Assuming the higher $S \sim 0.007 \, s^{-1}$ induced by the SFSBW northward velocity $V \sim 40 \, cm \, s^{-1}$, as measured in January 2010 (not shown), the $O(Ri) = 1.4$ might possibly allow for turbulent mixing, taking into account reduced salinity (density) stratification in winter due to sea-ice formation. While it cannot be shown explicitly that shear instability is entirely responsible for the enhanced vertical mixing, it may play a role in facilitating upward fluxes from the AW over the SAT eastern slope.

4.2 Heat loss from the AW in the SAT: estimates

In 2009, the heat content of the SFSBW inflow over the western SAT flank computed relative to the freezing temperature between 30 to 90 m depth decreased by $\sim 340\,\mathrm{MJ\,m^{-2}}$ upon reaching the eastern flank. For example, at 81° N the heat content

5 between 30 to 90 m depth decreased from 796 MJ m^{-2} at st. 23 (SFSBW inflow) to 457 MJ m^{-2} at st. 25 (SFSBW outflow). We note, however, the contrary tendency of the heat content over the eastern SAT between sts. 25 and 77, showing increase from 457 MJ m^{-2} at st. 25 to 584 MJ m^{-2} at st. 77 (Fig. 2). This discrepancy seems to be attributed to a crude spatial resolution of our time snapshot CTD data, which are insuf-

10 ficient to resolve the relatively narrow jet of the AW outflow from the SAT with horizontal temperature cross-slope gradients exceeding 1 °C/10 km (not shown).

In the following, we assume that all heat loss in the SFSBW occurs along the SAT eastern flank downstream of the SFSBW confluence with the Barents Sea water outflow to the SAT at $\sim 78°$ N. This assumption is based on the hypotheses that the

15 SFSBW heat loss is primarily driven by the velocity shear over the SAT eastern flank that is in line with model simulations showing no velocity shear over the SAT western flank (Fig. 7). This suggestion also implies neglecting the double diffusive heat loss from the AW over the SAT western flank, which is justified by the typical double diffusive heat flux estimated in the Arctic Ocean to 0.6 W m^{-2} (Sirevaag and Fer, 2012).

20 Moreover, this assumption is also based on the structure of the temperature profiles, showing that the major part of the deepening of the upper SFSBW interface occurs from 81° N on the western flank to 81° N on the eastern flank (Fig. 4). Furthermore, we neglect the lateral heat loss, particularly by a fraction of the SFSBW flowing west along the shallower trough between Novaya Zemlya and Franz Josef Land – Fig. 1 (e.g.,

25 Schauer et al., 2002a; Gammelrød et al., 2009). The travel time along the eastern SAT flank between 78° N and the mooring location at 81° N is estimated using northward along-trough velocities simulated with the MIT model. At each grid node over the eastern flank, the simulated velocity profiles were averaged from 2003 to 2010 (Fig. 6c).

The mean velocity profile computed from averaging all individual profiles over the eastern SAT shows $\sim 10\,\mathrm{cm\,s}^{-1}$ northward velocity for the SFSBW core at $\sim 90\,\mathrm{m}$ (Fig. 6c). This velocity implies a ~ 40 day travel time from 78° N to 81° N along the SAT eastern flank, the area where the heat content of the SFSBW was suggested to reduce by $\sim 340\,\mathrm{MJ\,m}^{-2}$. This is equivalent to an upward vertical heat flux from the SFSBW to the low halocline water of $\sim 100\,\mathrm{W\,m}^{-2}$. This rough estimate is similar to those reported by Sirevaag and Fer (2009) for the area north of Svalbard where the upward heat loss from the AW is among the largest throughout the Arctic Ocean (e.g., Steele and Morison, 1993). For comparison, over the Laptev Sea continental margins, Polyakov et al. (2012) estimated the heat flux across the upper AW interface of $\sim 8\,\mathrm{W\,m}^{-2}$. Microstructure measurements over the Laptev Sea continental shelf break reveal upward heat fluxes of $12\,\mathrm{W\,m}^{-2}$ (Lenn et al., 2011). Over the SAT eastern flank, our model simulations show a mean upward heat flux across the upper SFSBW interface with values in the range 30–$50\,\mathrm{W\,m}^{-2}$ (Fig. 8) that is about half or less the heat loss compared with estimates inferred from CTD observations in the SAT. This difference indicates that the double diffusive heat loss over the SAT western flank and the lateral heat loss might be also important. On the other hand, the model presents a large spatial and temporal variability in the vertical heat fluxes at the upper SFSBW interface, with values at times exceeding $100\,\mathrm{W\,m}^{-2}$. Therefore the inconsistency to the observations might be, in part, attributed to unresolved temporal variability. An incomplete model's mixing scheme might also provide an explanation for model-observational discrepancies.

4.3 Heat loss from the AW in the SAT: impact on sea ice

In what follows we test our hypothesis of enhanced SFSBW heat loss in the SAT by using sea-ice remote sensing data. The fraction of the AW heat expended for heating the overlaying water depends on the characteristics of the Barents Sea outflow. However, any upward heat flux reaching the sea surface will eventually affect the ocean–sea ice–atmosphere interface (e.g., through reduced sea-ice thickness, enthalpy flux to the atmosphere and delayed freeze-up). The winter mean (February–March) sea-ice

thickness derived from five ICESat winter campaigns in 2004–2008 (Kwok et al., 2009) shows an area with negative anomalies of ~ 20 cm that stretches from the SAT mouth towards Severnaya Zemlya following the Nansen Basin continental margin (Fig. 9a). This is consistent with simulated velocity difference in Fig. 7 and enhanced upward heat loss along the SFSBW pathway (Fig. 8). In February–March 2004–2008, the ice drift over the SAT mouth is mainly westward with a mean velocity of ~ 4 km day^{-1} (Fig. 9b and c). The mean width of the SAT eastern slope at the SAT mouth is ~ 50 km. This yields a ~ 12.5 days pack ice residence time over the SAT eastern slope at 82.5° N, where pack ice is exposed to the enhanced upward vertical heat flux from the SFSBW. The 20 cm sea-ice decrease in 12.5 days requires an upward heat flux of ~ 60 W m^{-2} to the ice–water interface, which is similar to that obtained from the model simulations (Fig. 8).

The time series of ice concentration across SAT at 81° N reveals later freeze-up and earlier sea-ice decline at the eastern flank (73° E; mooring position), lagging the more western and eastern locations at 68° E and 78° E, respectively, by ~ 0.5–2.5 months (Fig. 10). This is in agreement with simulated sea-ice concentrations showing consistent reduction over the SAT eastern flank during freeze-up (October, contours in Fig. 7c) and melting (June, contours in Fig. 7d). For estimating the sea-ice growth during freeze-up, we use the semi-empirical method based on an analytical model known as the classical Stefan's law (Stefan, 1891) that links the thermodynamic sea-ice growth to the cumulative surface air temperature below freezing. The accumulated sea-ice growth time series for 2005–2011 computed based on the surface air temperature from the NCEP reanalysis are shown in Fig. 11. For simplicity, we focus on satellite overpass times where the estimated thermodynamic sea-ice growth reaches ~ 20 cm, which roughly corresponds to the fall and winter sea-ice thickness anomaly over SAT in Figs. 7a and 9a, respectively. In contrast to the expected thermodynamic sea-ice growth of ~ 20 cm, the SAT eastern flank remains ice free even during the late fall at air temperatures far below freezing (~ -15 °C). For instance, on 25 October 2005 (Fig. 12a) the NCEP-derived daily mean air temperature was as low as -14 °C, which

corresponds to a thermodynamic sea-ice growth of $\sim 2\,\mathrm{cm\,day}^{-1}$ (Fig. 11). Melting this amount of ice requires $\sim 70\,\mathrm{W\,m}^{-2}$ that approximately fits the upward heat flux inferred from the model simulation (Fig. 8). We note that this approach overestimates the heat loss because the Stefan's does not account for solar insolation.

5   The observed ice-free area, stretching along the SAT eastern flank (Fig. 12), is fully consistent with our assumption of a substantial AW heat loss along the eastern flank corroborated by a model simulation. Figure 12 is also in agreement with simulated sea ice thickness and concentration showing significant reduction over the SAT eastern flank in October (Fig. 7a and c). Another remarkable feature of sea ice in the SAT is

10   that in 2005, 2007, 2008, 2009 and 2011 the area of reduced sea-ice concentration (45–85 %) was stretched along the SAT eastern flank further north to the SAT mouth at $\sim 82°\,\mathrm{N}$ where it turned east following the Nansen Basin continental slope (e.g., Fig. 12c). This is also in line with (i) the spatial distribution of sea ice thickness anomaly in Fig. 9a and (ii) the enhanced AW heat loss simulated along the Kara Sea continental

15   slope (Fig. 8).

The BSBW, entering the Arctic Ocean along the SAT, can also potentially impact the sea ice in this region (compare the BSBW pathway and configuration of the open water area in the SAT – Figs. 1 and 12). At the Barents Sea exit between Novaya Zemlya and Franz Josef Land, Årthun and Schrum (2010) simulated a long-term mean surface heat

20   flux from the ocean of $\sim 10\,\mathrm{W\,m}^{-2}$, which modifies the ice cover distribution as shown in Årthun et al. (2012). However, en route to the SAT, the warm core of the BSBW with temperatures above 0° and salinities between 34.8–35 psu is decoupled from the sea surface occupying the depths deeper than 70–100 m (Gammelsrød et al., 2009; Lien and Trofimov, 2013). Within the SAT, the warm BSBW core submerges even below the

25   SFSBW (e.g., Dmitrenko et al., 2008, 2009). This suggests that the BSBW does not play a role in modifying the sea-ice conditions over the SAT through direct heat loss.

5 Summary and concluding remarks

We have shown that the St. Anna Trough is one area of the Arctic Ocean where AW heat loss can modify the ocean–sea ice–atmosphere interface affecting both the formation and decay of sea ice. In this sense, the St. Anna Trough is generally similar to an
5 "ice bay" known as Whalers' Bay formed by inflowing Fram Strait branch of AW north of Svalbard (e.g., Ivanov et al., 2012). The sheared St. Anna Trough outflow to the Arctic Ocean is evident from shipboard ADCP as well as from geostrophic velocities and numerical model simulations. Although no clear evidence for the occurrence of shear instabilities could be obtained, we speculate that the enhanced upward heat flux in the
10 St. Anna Trough is promoted by a vertical velocity shear along the St. Anna Trough eastern flank. We show that the zone of lowered sea ice thickness and concentration essentially marks the Fram Strait branch pathway in the St. Anna Trough and adjacent Nansen Basin continental margin from both sea-ice remote sensing observations and model simulations.

15 Our analysis was significantly limited by the availability of velocity data, and our heat flux estimates based on CTD observations were necessarily illustrative. Our cross-trough CTD transects are time snapshots, and the crude spatial resolution is insufficient to resolve the jet of the AW outflow from the St. Anna Trough. We also note that our estimates of the heat flux at the ice–water interface using sea-ice remote sensing
20 show a lower bound because water and sea-ice dynamics are not taken into account. Moreover, we note that heat loss from the St. Anna Trough recirculating Fram Strait branch is not entirely available for sea-ice melt, and its important fraction is likely to be consumed for modifying the overlaying water and atmospheric boundary layer. We note that although Stephan's law is a simplification of the requisite physics it does provide
25 first-order agreement in our observed surface temperature fluxes and the thermodynamic response of the sea ice. Finally, the deficiencies of our analyses clearly define a necessity for further research in this area to quantify the efficiency of shear instability

Heat loss from the Atlantic water layer

I. A. Dmitrenko et al.
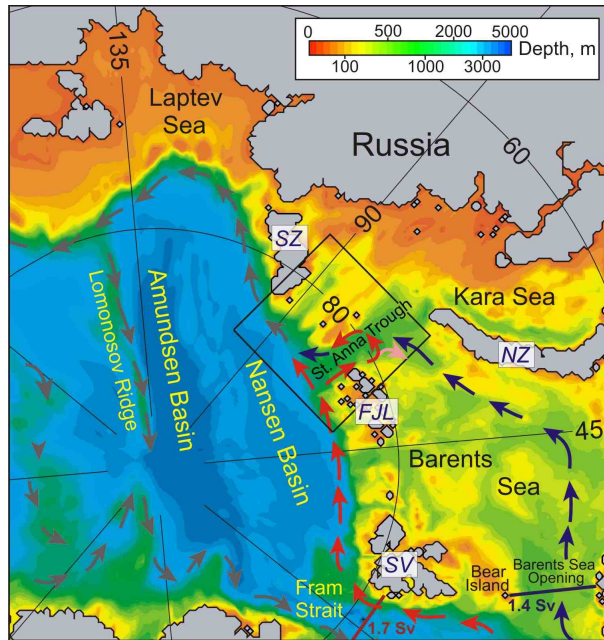

Fig. 1. Map of the inflow region of Atlantic Water (AW)_to the Arctic Ocean. Arrows trace the Atlantic water (AW) pathways; red and blue arrows show the Fram Strait and Barents Sea branches, respectively, of the AW inflow into the Arctic Ocean in accordance with Rudels et al. (1994). The pink arrow shows a fraction of the Fram Strait branch water flowing west along the shallower trough between Novaya Zemlya and Franz Josef Land. Dark red and blue numbered lines in Fram Strait and Barents Sea Opening, respectively, show sections used for verifying the simulated volume transport of AW. Dark blue number indicates the simulated volume transport of AW (defined as $T > 3\,°C$) through the Barents Sea Opening. Dark red number shows the simulated volume transport of AW (defined as $T > 2\,°C$) in the core of the West Spitzbergen Current. The black rectangle encloses the region enlarged in Fig. 2. *SV* – Svalbard, *FJL* – Franz Josef Land, *NZ* – Novaya Zemlya, *SZ* – Severnaya Zemlya.
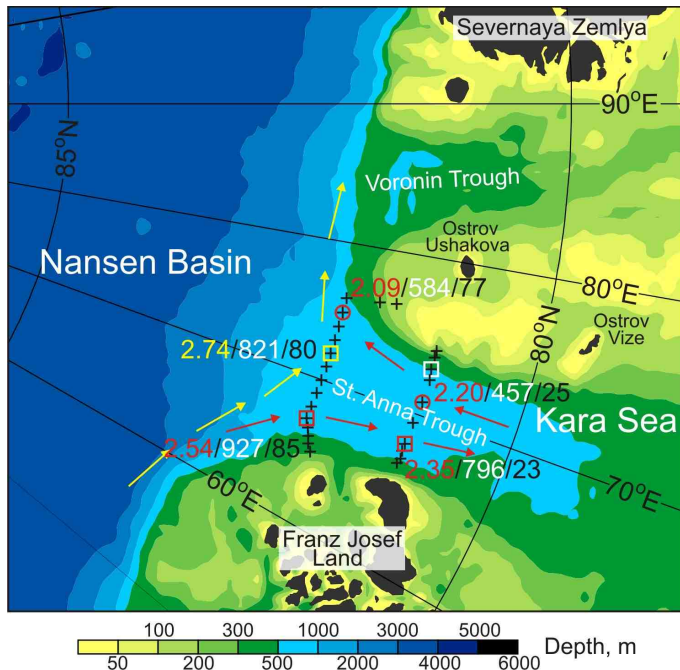

Fig. 2. A map of the northern Kara Sea with the St. Anna Trough (SAT). Arrows show the Fram Strait branch of the AW inflow into the Arctic Ocean that recirculates in the SAT (red arrows, SFSBW) and follows the continental margin (yellow arrows, FSBW). Crosses depict the positions of CTD stations taken in September 2009 at two sections crossing the SAT at ~ 81° N and 82° N. Red squares and circles identify stations taken through the core of the SFSBW inflow and outflow to/from the SAT, respectively. The yellow square identifies station taken through the core of the FSBW boundary current. The white square depicts mooring position. The first (yellow/red) number shows the FSBW/SFSBW core temperature (°C) in September 2009. The second (white) number is heat content (MJ m^{-2}) computed relative to the freezing temperature between 30 to 90 m depth. The third (black) number denotes station number.

Fig. 3. Simulated and observed characteristics of the AW inflow into the Arctic Ocean through the (left) Barents Sea Opening from Bear Island to Norway (BSO) and (right) Fram Strait. The first row shows the simulated mean temperature (in color) and velocity (contour lines) in **(a)** the Fram Strait from 2002 to 2008, as in Beszczynska-Moeller et al. (2012) and **(b)** the BSO from 2003 to 2005, as in Skagseth (2008). Positive velocities in **(a)** and **(b)** are to the East and North, respectively. **(c)** Temperature in the AW layer (blue – model, green – observations) defined as mean between 72–73° N and 50–200 m and in the outflow water in the Bear Island Trough (red – model, cyan – observations) at 73.5° N, defined as the mean from 300–450 m. Definitions and observational data are from Skagseth (2008). **(d)** The AW mean temperature in the core of the West Spitzbergen Current (WSC) from the model (blue) and observations (green), defined as waters with $T > 2$°C between 8° E and 8°40′ E. Definition and observational data are from Beszczynska-Moeller et al. (2012). **(e)** The AW (defined as $T > 3$°C) volume transport through the BSO as simulated by the model (blue) with the 1997–2006 mean from observations (green) superimposed (Skagseth et al., 2008). **(f)** The AW volume transport in the WSC (AW defined as in **d**), from the model (blue) and observations (green) by Beszczynska-Moeller et al. (2012).
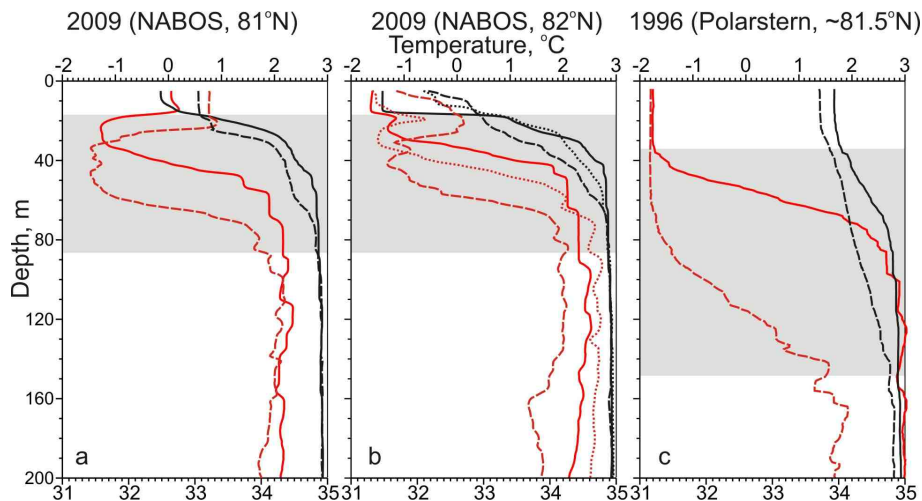

Fig. 4. Vertical profiles of temperature (red, °C) and salinity (black, psu) in the upper 200 m layer taken in July 1996 and September 2009 through the core of SFSBW inflow (solid line, left – st. 23, center – st. 85, right – 81°27′ N, 65°51′ E) and outflow (dashed line, left – st. 25, center – st. 77, right – 81°17′ N, 72°01′ E) to/from the SAT. **(b)** The dotted line depicts the CTD profile taken in September 2009 through the core of the FSBW boundary current (st. 80). For station positions in 2009 see Fig. 2. Gray shading highlights outflow from the SAT modified by vertical mixing.
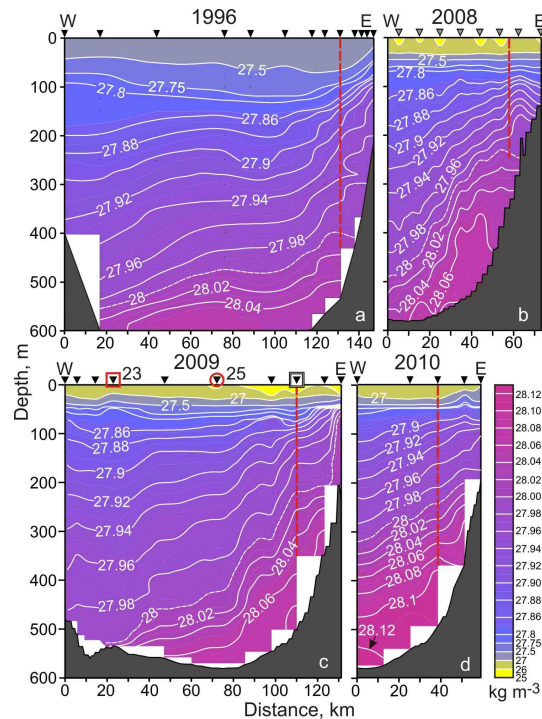

Fig. 5. 10 m binned cross-trough sections of potential density (σ-zero, kg m^{-3}) along 81° N for **(a)** July 1996, **(b)** September 2008, **(c)** September 2009 and **(d)** October 2010. Black and gray triangles on the top identify positions of CTD and XCTD stations, respectively. Following Fig. 2, the red square and circle and the white square identify stations taken through the core of the SFSBW inflow and outflow to/from the SAT and mooring position, respectively, with their reference numbers on the top. Red dashed lines identify locations of the geostrophic velocity profiles shown in Fig. 6a. The white dashed line highlights σ-zero = 28 kg m^{-3} that roughly corresponds to the core of the cooler fraction of BSBW (Dmitrenko et al., 2008, 2009).
