Abstract

Information on recent photosynthetic biomass distribution and biogeography with adequate temporal and spatial resolution is urgently needed to better understand consequences of environmental change for marine ecosystems. Here we introduce and review a molecular-based observation strategy for high resolution assessment of marine protists in space and time. The observation strategy is the result of extensive technology developments, adaptations and evaluations which are documented in a number of different publications and the results of recently accomplished field testing, which are introduced in this review. The observation strategy is organized in four different levels. At level 1, samples are collected in high spatio-temporal resolution using the remote-controlled automated filtration system AUTOFIM. Resulting samples can either be preserved for later laboratory analyses, or directly subjected to molecular surveillance of key species aboard the ship via an automated biosensor system or quantitative polymerase chain reaction (level 2). Preserved samples are analyzed at the next observational levels in the laboratory (level 3 and 4). This involves at level 3 molecular fingerprinting methods for a quick and reliable overview of differences in protist community composition. Finally, selected samples can be subjected to generate a detailed analysis of taxonomic protist composition via latest Next Generation Sequencing (NGS) at level 4. An overall integrated dataset of the results based on the different analyses provides comprehensive information on the diversity and biogeography of protists, including all related size classes. At the same time the cost effort of the observation is optimized in respect to analysis effort and time.

1 Introduction

It is expected that marine ecosystems will be affected by climate change in multiple ways, including rising atmospheric CO_2 levels, shifts in temperature, circulation, stratification, nutrient input, oxygen content, and ocean acidification. In summary, these changes will strongly impact marine biota and ecosystems with consequences for abundance, diversity, spatial distribution, biogeography, or dominance of marine species (Doney et al., 2012). Marine plankton, comprising prokaryotic and eukaryotic microbes (bacteria and protists) as well as small or juvenile metazoans, is of utmost importance for the functioning of marine ecosystems. It is traditionally divided by its size into three classes: The microplankton (>20µm), the nanoplankton (20-2 µm), and the picoplankton (<2 µm). Within these groups of organisms, phytoplankton as the photosynthetic active part of the plankton accounts for roughly half of global net primary productivity (NPP) (Field et al., 1998) and is fundamental for any marine ecosystem function or service. As a consequence, changes in phytoplankton community structures and biogeography as a response to climate change are currently driving topics in marine ecology. Moreover, marine phytoplankton is very well suited to serve as an indicator of climate change (Nehring, 1998), because its dynamics are closely coupled to environmental conditions (Acevedo-Trejos et al., 2014). Despite the necessity and advantage of using marine phytoplankton to assess consequences of climate change, the task is also challenging in various ways. Marine phytoplankton distribution displays high spatial heterogeneity or "patchiness" (Mackas et al., 1985) and a pronounced seasonality as a consequence of physical and chemical oceanographic processes (Boersma et al., 2016; Bresnan et al., 2015). Furthermore, there are difficulties with the taxonomic surveillance of species in the pico-, or nano-fraction, related to their cell size and insufficient morphological features. As a consequence it is very challenging to provide information on composition, occurrence, and dynamics of phytoplankton with adequate spatial and temporal resolution. Together with the difficulties to financially support and maintain long time series these challenges might account for the relatively small number of marine phytoplankton long-term time series worldwide. Among them, one long lasting time series, the Helgoland Roads Time Series, is maintained by the Alfred Wegener Institute Helmholtz Centre for Polar- and Marine Research at the island Helgoland in the German Bight (North Sea). The dataset comprises information on abundance of phytoplankton on a daily basis since 1962 (Kraberg et al., 2015; Wiltshire et al., 2009). However, it does not provide information on the abundance of the smallest phytoplankton species and is restricted to one sampling point. The latter restriction is overcome by a second major long term marine observation programme that is operated by the Sir Alistair Hardy Foundation for Ocean Science in Plymouth, UK: the **C**ontinuous **P**lankton **R**ecorder (CPR) Survey's marine observation programme (McQuatters-Gollop et al., 2015). Together with its sister surveys it provides large-scale information on marine plankton distribution, mainly in the North Atlantic and the North Sea since the first surveys in 1931. Unfortunately, the CPR-approach is restricted to zooplankton and bigger phytoplankton e.g. diatoms. Again, the ecological relevant phytoplankton of the pico- and nanoplankton fraction is omitted. However, the smaller phytoplankton is to a certain degree included in the surveys of the FerryBox project implemented by the Helmholtz Centre Geesthacht in the North Sea. A FerryBox is an autonomous device located on ships of opportunity that has the capability to autonomously generate information on the plankton composition and a number of other parameters for the North Sea (Petersen, 2014). Here, phytoplankton is characterized on the basis of the pigment composition present, which is estimated via multi-channel fluorescence measurements. All phytoplankton groups and size fractions are included in this analysis, but this approach is only suited for the identification of larger taxonomic algal

Ocean Sci. Discuss., doi:10.5194/os-2016-23, 2016
Manuscript under review for journal Ocean Sci.
Published: 23 May 2016

groups. Furthermore, spectrally similar groups (e.g. diatoms and dinoflagellates) cannot be distinguished by this method. Thus the FerryBox project lacks information on species composition of phytoplankton.

Overall, these long term monitoring programmes and other current marine plankton observation approaches have already given important information and indication on climate related change in the marine plankton community. Nevertheless, each of them is limited in one or the other way: (i) the ongoing long time series are mainly limited to one or small numbers of sampling points; (ii) they do not provide a holistic view of changes at the base of marine food webs, because they neglect the pico- and nanoplankton fractions; (iii) broad taxonomic knowledge is required for the identification of taxa at species level; (iv) fluorescent characterization of phytoplankton is restricted to the identification of larger taxonomic groups; (v) they are costly if larger numbers of samples need to be processed.

In respect to these shortcomings and challenges of current observation approaches, it is of utmost importance to develop efficient automated high throughput approaches and observation strategies that allow reliable surveillance of all phytoplankton size classes with adequate spatio-temporal resolution. Over the past decade numerous publications demonstrated the power of a large variety of molecular methods for observation of marine plankton organisms, especially of those that are missing distinct morphological features (Metfies et al., 2010; Wolf et al., 2014a; Wollschlaeger et al., 2014). Previous publications have shown the power of the analysis of ribosomal genes (rRNA-genes) to gain new insights into the phylogeny and biogeography of prokaryotic and eukaryotic micro-organisms (Sunagawa et al., 2015). The genes coding for the rRNA are particularly well suited for phylogenetic analysis and taxonomical identification, because they are universally present in all cellular organisms. Furthermore, rRNA genes are of relatively large size and contain both highly conserved and variable regions with no evidence for lateral gene transfer (Woese, 1987). The continually growing number of available algal 18S rDNA-sequences, e.g. in the Ribosomal Database Project (Quast et al., 2013), and phylogenetic analysis makes it possible to design hierarchical sets of probes that specifically target the 18S-rDNA of different taxa (Metfies and Medlin, 2007; Thiele et al., 2014). The probes can be used in combination with a wide variety of hybridization based methods, such as RNA-based nucleic acid biosensors (Diercks et al., 2008a; Ussler et al., 2013) quantitative PCR (Bowers et al., 2010; Toebe et al., 2013) or fluorescence *in situ* hybridization (FISH) (Thiele et al., 2014). Other methods, such as molecular fingerprinting approaches and Next Generation Sequencing provide information on variability and composition of whole microbial communities. The molecular fingerprinting method **A**utomated **R**ibosomal **I**ntergenic **S**pacer **A**nalysis (ARISA) is a quick, cost-effective and meaningful method to determine overall variability in phytoplankton community composition (Kilias et al., 2015) that is independent of the size or morphology of target organisms. In contrast, NGS of ribosomal genes allows high resolution, taxon-specific assessments of protist communities, including their smallest size fractions and the rare biosphere (de Vargas et al., 2015; Kilias, 2014).

Here, we introduce a combined molecular-based observation strategy that allows observation of current phytoplankton composition, distribution, and dynamics at adequate spatial and temporal scales. The resulting data sets can be used to estimate possible alterations related to climate or environmental change. Our strategy is the result of technical developments and the integration of latest sampling- and molecular tools in an advanced molecular-based observation approach that will optimize marine microbial observation in general, while phytoplankton was in the focus of our developments. In the future our molecular observation strategy is intended to cut down surveillance costs and provide information on marine microbial biodiversity with unprecedented resolution. It is a development of the Helmholtz Young Investigators Group PLANKTOSENS (Assessing

Climate Related Variability and Change of Planktonic Foodwebs in Polar Regions and the North Sea) carried out within the framework of COSYNA (Coastal Observing System for Northern and Arctic Seas). Here, we review major published results that lead to the development of the molecular observation strategy and demonstrate the applicability of newly developed sampling technology within the observation strategy. Special emphasis was put on observation of Arctic pico-phytoplankton that constitutes a major contribution to pelagic Chl *a* biomass during summer (Metfies et al., 2016).

2 Material and Methods

2.1 Sampling

Water samples analyzed in this study were collected during expeditions PS85 (June 2014) and PS96 (May/June 2015) of RV Polarstern to the Arctic Ocean. Samples from deeper water layers containing the deep chlorophyll maximum (DCM) were taken with a rosette sampler equipped with 24 Niskin bottles (12 L per bottle) and sensors for Chl *a* fluorescence, temperature and salinity (CTD). Samples collected via CTD were taken during the up-casts at the vertical maximum of Chl *a* fluorescence determined during the down-casts. The sampling depths varied between 10–50 m. Two liter subsamples were taken in PVC bottles from the Niskins. Particulate organic matter for molecular analyses was collected by sequential filtration of one water sample through three different mesh sizes (10 µm, 3 µm, 0.4 µm) on 45 mm diameter Isopore Membrane Filters at 200 mbar using a Millipore Sterifil filtration system (Millipore, USA).

Additional samples were collected from a depth of ~ 10 m with the **Auto**mated **fi**ltration device for **m**arine microorganisms AUTOFIM, which is coupled to the ships pump system. Here, two liter sea water were collected and filtrated on a filter with 0.4 µm pore size at 200 mbar. Subsequent to filtration, particulate organic matter on the filter was re-suspended with 600 µl Lysis Buffer RLT (Qiagen, Germany) and stored at -80°C until further processing in the laboratory.

2.2 Environmental parameters

Standard oceanographic parameters (salinity, temperature, Chl *a* fluorescence, turbidity, chromophoric dissolved organic matter, dissolved oxygen, pH, nutrients) were measured at the sampling sites by the FerryBox-System (Petersen, 2014) deployed on board RV Polarstern. The measurement interval was 1 min, and the water intake of the system was identical to the water supply of AUTOFIM. To prevent biofouling of the sensors, the FerryBox performed a cleaning cycle including an acid wash and freshwater rinsing once per day.

2.3 DNA isolation

Isolation of genomic DNA from the field samples was carried out using the E.Z.N.A TM SP Plant DNA Kit Dry Specimen Protocol (Omega Bio-Tek, USA) following the manufacturer's protocol. The resulting DNA-extracts were stored at -20 °C.

Ocean Sci. Discuss., doi:10.5194/os-2016-23, 2016
Manuscript under review for journal Ocean Sci.
Published: 23 May 2016

170 **2.4 DNA quality**

171 The integrity of the genomic DNA isolated from water samples collected with AUTOFIM was assessed using
172 the Agilent DNA 7500 kit (Agilent Technologies, USA) according to the manufacturer's protocol. A volume of
173 1µl DNA was applied to the flow cell.

174 **2.5 ARISA**

175 PCR-amplification and subsequent determination of the size of the PCR fragments, and statistical analyses
176 related to ARISA were accomplished as described previously in the studies contributing to the development of
177 the molecular observation strategy (e.g. Kilias et al., 2015). This included the determination of variability in the
178 length of the intergenic spacer region 1 (ITS1) amplified via a specific primer set from genomic DNA extracted
179 from field samples.

180 **2.6 454-Pyrosequencing**

181 Sequencing of protist communities via 454-pyrosequencing was based in all studies reviewed in this manuscript
182 on amplification of a ~ 670 bp fragment of the 18S rDNA containing the hypervariable V4 region Sequence
183 library preparation and data analysis was described previously in the studies contributing to the development of
184 the molecular observation strategy (e.g. Kilias et al., 2013; Metfies et al., 2016). .

185 **2.7 Quantitative PCR-assay**

186 The quantitative PCR was carried out in a nested two step approach. In the first step total eukaryotic 18S rDNA
187 was amplified using the universal primer-set 1F-(5´-AAC TGG TTG ATC CTG CCA GT-3´) / 1528R- (5´-TGA
188 TCC TTC TGC AGG TTC ACC TAC-3´) (modified after Medlin et al., 1988). PCR-amplifications were
189 performed in a 20 µl volume in a thermal cycler (Eppendorf, Germany) using 1x HotMasterTaq buffer
190 containing Mg^{2+}, 2.5 mM (5´Prime); 0.5 U HotMaster Taq polymerase (5´Prime, Germany); 0.4 mg/ml BSA; 0.8
191 mM (each) dNTP (Eppendorf, Germany); 0.2 µM of each primer (10 pmol/µl) and 1µl of template DNA (20
192 ng/µl). The amplification was based on 35 cycles, consisting of 94°C for 1 min, 54°C for 2 min and 72°C for 2
193 min, followed by 1 min denaturation at 94°C and finalized by a final extension of 10 min at 72°C. Subsequently
194 PCR products were purified using the QIAquick PCR purification kit (Qiagen, Hilden, Germany). In the second
195 step a qPCR-assay was carried out using a species specific primer-set 82F-(5´-GTG AAA CTG CGA ATG GCT
196 CAT-3´) / P1np- (5´-CGG GCG GAC CCG AGA TGG TT-3´) for *Phaeocystis pouchetii*. The quantitative PCR-
197 assays were performed in a 20 µl volume in a 7500 Fast Real-Time PCR-System (Life Technologies
198 Corporation; Applied Biosystems, USA) using 1x SYBR Select Mastermix (Life Technologies, USA); 0.2 µM
199 of each primer (10 pmol/µl) and 2µl of the purified 18S rDNA PCR-fragment. The amplification was based on
200 40 cycles, consisting of 95°C for 10 min, 95°C for 15 sec, 66°C for 1 min. The quantitative PCR-assay was
201 calibrated with a dilution series of a laboratory culture of *Phaeocystis pouchetii*. Based on this calibration CT-
202 values were transformed into cell numbers using the following equation:
203 CT= -2.123 ln (cell numbers) + 38.788.

3 Results and Discussion:

3.1 Overview Molecular Based Observation Strategy

The molecular based observation strategy that we present here is organized in 4 different levels (Figure 1). At level 1, samples are collected in high spatio-temporal resolution using the remote-controlled automated filtration system AUTOFIM (Figure 2). The sampling system can either be deployed on a fixed monitoring platform or aboard a ship (research vessel or ship of opportunity). Samples can be preserved for later laboratory analyses, or directly subjected to molecular surveillance of key species aboard the ship via an automated biosensor system or quantitative polymerase chain reaction (level 2). Direct analyses aboard ships provide near real time information on abundance and distribution of phytoplankton key species that can be used to optimize phytoplankton sampling for detailed high resolution analyses of overall phytoplankton composition during an ongoing sampling campaign. The resulting preserved samples will be analyzed at the next observational levels in the laboratory (level 3 and 4). This involves at level 3 molecular fingerprinting methods that provide a quick and reliable overview of differences in protist community composition of the samples in a given observation area or time period. Furthermore, this information can be used to select representative samples for detailed analysis of taxonomic protist composition via latest next generation sequencing at level 4. An overall integrated dataset of the results based on the different analyses provides comprehensive information on the diversity and biogeography of protists, including all related size classes. At the same time, the cost effort of the observation is optimized in respect to analysis effort and time. Sampling based on the autonomous filtration device is more cost efficient, because labor costs and the requirement of ship space and time are reduced.

The development of the Molecular Observation Strategy was based on extensive method development and evaluation. Overall, it included: (i) the development of an automated remote controlled filtration system (Figure 2, (ii) the evaluation and application of **A**utomated **R**ibosomal **I**ntergenic **S**pacer **A**nalysis (ARISA) (Kilias et al., 2015), (iii) the implementation of Next Generation Sequencing (454-pyrosequencing; Illumina) for marine protists (e.g. Wolf et al., 2013) and (iv) the development and evaluation of molecular probe based methods such as molecular sensors (Wollschlaeger et al., 2014) or quantitative PCR (qPCR). Most of the field work presented here in this publication was accomplished in the Arctic Ocean with special emphasis on the area of the "Deep-Sea Long-Term Observatory Hausgarten" established by the Alfred Wegener Institute for Polar- and Marine Research in 1999 to carry out regular observations of the ecosystem in the eastern Fram Strait (Soltwedel, 2005). In the following, the different parts of the observation strategy are presented in detail.

3.1.1 Automated remote controlled filtration system

The remote controlled **auto**mated **fi**ltration system for **m**arine microbes (AUTOFIM) is the core of the observation strategy. The filtration system (Figure 2) can be operated autonomously aboard research vessels or ships of opportunity. AUTOFIM allows filtration of a sampling volume up to five litres from the upper water column. In total, 12 filters can be taken and stored in a sealed sample archive. Prior to storage, a preservative is applied to the filters preventing degradation of the sample material, that can be used for molecular or biochemical analyses. Exchanging the sample archive is a quick and easy task, which makes it feasible for lay persons from the ships´ staff to take care of the automated filtration. This would circumvent the need to provide support of an additional specifically trained personal for filtration in the field. Filtration can be triggered after

Ocean Sci. Discuss., doi:10.5194/os-2016-23, 2016
Manuscript under review for journal Ocean Sci.
Published: 23 May 2016

defined regular time intervals or remote controlled from a scientist at the research institute. Additionally, it could also be event-triggered if the filtration system would be operated in connection with *in situ* sensor systems (Petersen, 2014). Overall, AUTOFIM provides the technical background for automated high spatio-temporal resolution collection of marine particles e.g. for molecular analyses. During expedition PS92 of RV Polarstern to the Arctic Ocean in summer 2015, AUTOFIM was used for the first time to collect samples from the upper water column at a depth of ~ 10 m, which is the depth of the inlet of the ships water pump system. Subsequent to filtration, samples were preserved with a preservation buffer and stored at -80°C until further analyses in the laboratory.

3.1.2 Automated Ribosomal Intergenic Spacer Analysis (ARISA)

ARISA provides information on variability in protist community structure in larger sample sets at reasonable costs and effort, while ARISA-profiles reflect taxon specific differences observed in NGS-data sets (Kilias et al., 2015). In the developmental phase of the molecular observation strategy, this method was used in a number of different studies to better understand variability of Arctic marine protist communities in relation to environmental conditions and ocean currents. Based on ARISA analyses we identified large scale patterns of protist biogeography that were tightly connected to ambient water masses, ocean currents and sea ice coverage (Kilias et al., 2014a; Metfies et al., 2016; Wolf et al., 2014b). We suggest to use ARISA as part of the molecular observation strategy to identify biogeographic or biodiversity patterns at meso- or large in large sample sets, e.g. collected via AUTOFIM. However, spatial heterogeneity of marine phytoplankton is large, while the vertical dimension is from particular importance, since differences in vertical abundance and composition of phytoplankton impact primary production, export processes and energy transfer to higher trophic levels (Leibold, 1990). Vertical distribution of marine protists is determined by opposing resource gradients and mixing conditions (Mellard et al., 2011). In respect to this it was necessary to evaluate how representative samples from 10 m depth might be for the underlying water column. This would be important in case AUTOFIM would be applied to study large scale biogeographic patterns of marine protists. Acknowledging the potential of ARISA to quickly generate meaningful information on variability between protist samples, we used this methodology to assess the similarity of phytoplankton community composition in samples from the upper water column collected with AUTOFIM and in samples collected in deeper water layers via CTD. The ARISA patterns obtained from deeper horizons are highly similar to those obtained from the samples collected with AUTOFIM. The samples collected with AUTOFIM at stations PS92/19 and PS92/43 clustered together with the indivdual samples collected at deeper horizons (5m; 20m; 50m) and the integrated signal from all three depths at the same station (Figure 3). This result suggests that qualitative information on phytoplankton community composition based on sampling with AUTOFIM might be representative for the photic layer of the water column. This might be attributed to the observation that geography and ambient water masses have a major impact on qualitative composition of marine plankton communities on a larger scale, with plankton communities being partially structured according to basin of origin (de Vargas et al., 2015; Metfies et al., 2016).

3.1.3 Next Generation Sequencing (454-pyrosequencing; Illumina)

Sequencing of ribosomal genes is a valuable approach to describe the taxonomic composition of protist communities including the small size fractions. Technical progress in this field has been tremendously rapid over

Ocean Sci. Discuss., doi:10.5194/os-2016-23, 2016
Manuscript under review for journal Ocean Sci.
Published: 23 May 2016

the last 5-10 years. Around ten to fifteen years ago, sequencing of 18S rDNA clone libraries was the gold standard to assess marine eukaryotic and prokaryotic communities (Hugenholtz, 2002). Around six years ago, first studies reported the use of 454 pyrosequencing for assessment of prokaryotic diversity (Turnbaugh et al., 2009). The massively parallel 454-pyrosequencing generated several hundred thousands of ribosomal sequence per sample and had the potential to uncover more organisms, even rare species from large scale biodiversity surveys (Sunagawa et al., 2015). We assessed the validity of 454 pyrosequencing by evaluating the sequence data sets with results obtained via other methods, such as 18S clone libraries, HPLC and microscopic counts. In our data sets pyrosequencing data were in good agreement with information on community composition generated by high pressure liquid chromatography (HPLC) or clone libraries (Kilias et al., 2013; Wolf et al., 2013). During the past six years, we used 454-pyrosequencing to determine variability of protist community structure in Fram Strait, in the area of the "Deep-Sea Long-Term Observatory Hausgarten", and the central Arctic Ocean (Kilias et al., 2014a; Metfies et al., 2016). Overall, our data revealed that *Phaeocystis pouchetii* is an important contributor to Arctic protist communities, particularly to the pico-eukaryote community composition. In 2009 the species constituted up to 29.6% of the sequence assemblage retrieved from pico-eukaryote samples collected in the area of the "Deep-Sea Long-Term Observatory Hausgarten" (Kilias et al., 2014b). A larger survey of Arctic protist community composition in 2012 including Fram Strait and larger parts of the Central Arctic Ocean confirmed these observations and identified *Phaecystis pouchetii* again as an important contributor to Arctic pico-eukaryote Chl *a* biomass, which constituted between 60-90% of Chl *a* biomass during summer 2012 in the Arctic Ocean (Metfies et al., 2016). This comprehensive sequence based information on phytoplankton community composition was very well suited to serve as a basis for the development of molecular probes that can be used for molecular surveillance with molecular sensors or quantitative PCR (qPCR).

3.1.4 Development and evaluation of molecular probe based methods such as molecular sensors or qPCR

Molecular Sensors are chip based formats that allow parallel identification and quantification of multiple taxa in a single experiment. The identification is based on solid phase hybridization of molecular probes, immobilized to the surface of the sensor chips to the rRNA or rDNA of the target species (Diercks et al., 2008a; Diercks et al., 2008b; Ussler et al., 2013). Quantitative or real time PCR (qPCR) is a standard PCR with the advantage of detecting the amount of DNA formed after each cycle with either fluorescent dyes or fluorescently-tagged oligonucleotide probes. Quantitative PCR is a useful tool for quantitation of nucleic acids in a given environment (Toebe et al., 2013). An automated molecular sensor (Diercks et al., 2008a) and qPCR are intended to be part of the molecular observation strategy in order to generate near real time information on the occurrence of key species on board ship and to complement NGS-based information on phytoplankton community composition with quantitative information on the occurrence of selected key species (Figure 1). These approaches are necessary because of biases related to the amplification of the 18S rDNA gene via PCR, and uncertainties in respect to copy number of the gene in the genome of different species, which make it difficult to deduce species abundance based on NGS. In respect to this, we developed new molecular probes for relevant taxa that were major contributors in our NGS-libraries or that were known from published literature to occur in the observation areas (North Sea and Arctic Ocean). The molecular probes were either used in combination with molecular sensors (Wollschlaeger et al., 2015), qPCR or fluorescent *in situ* hybridization (FISH) (Thiele et al., 2014). The

Ocean Sci. Discuss., doi:10.5194/os-2016-23, 2016
Manuscript under review for journal Ocean Sci.
Published: 23 May 2016

results of molecular sensors targeting either 18S rDNA or 18S rRNA were evaluated with the results obtained from microscopy, HPLC and flow cytometry (Wollschlaeger et al., 2014). The molecular sensor targeting 18S rRNA shows a robust linear relationship between molecular sensing signal and cell counts via microscopy. The positive evaluation results for the rRNA based nucleic acid biosensor suggest a high potential of the method to be used as module in a Molecular Observation Strategy. Here, the related regular monitoring would benefit from advantages like reduced effort, and the high potential for automation of the methodology (Wollschlaeger et al., 2014). In the current study we demonstrate the potential of quantitative PCR to better understand the biogeography and abundance of *Phaeocystis pouchetii* in Arctic Waters using a specific primer set for qPCR. The qPCR values were calibrated against defined numbers of laboratory cultures (Figure 4) to allow quantification of *Phaeocystis pouchetii* via this method. During expedition PS85 of RV Polarstern in June 2014, we used qPCR on board ship to determine the abundance of *Phaeocystis pouchetii* on a transect through Fram Strait at ~79°N (Figure 4). The results of our survey suggest that abundance of *Phaeocystis pouchetii* in Fram Strait is determined by water mass properties such as salinity, ice coverage and water temperature, while salinity is positively correlated with abundance of *Phaeocystis pouchetii*. The abundance of *Phaeocystis pouchetii* was higher in Atlantic Waters, which are characterized by higher salinities in the range of 33-34 PSU, than in Polar Waters of Fram Strait which are characterized by salinities around 31 PSU. In Atlantic Waters the average cell number of *Phaeocystis pouchetii* was ~ 3.5 times higher than the average cell number in Polar Waters of Fram Strait. Furthermore, Chl *a* biomass appears to be correlated with abundance of *Phaeocystis pouchetii*. Our findings are in agreement with previous studies that reported blooms of *Phaeocystis pouchetii* in waters around Svalbard with cell abundances in a similar range as observed in this study (Wassmann et al., 2005). In 2012, we carried out a large scale study to survey the biogeography of marine protists in the Arctic. This survey included a comprehensive NGS based analysis of community composition along 79°N in Fram Strait in June and later in the season in Nansen Basin and Amundsen Basin. Overall, the findings of 2014, suggesting a positive correlation of Atlantic water properties, e.g. higher salinity and lower ice coverage with high abundance of *Phaeocystis pouchetii* are in agreement with the previous study of 2012. This study also suggested this positive correlation, even though sequence abundance of *Phaeocystis pouchetii* was more evenly distributed in Fram Strait in that year (Metfies et al., 2016). This might be attributed to the complex current system in the area. Overall, qPCR carried out on board ship provided a near real time overview of the distribution of a protist key species during expedition PS85.

4 Conclusions

Here we introduce for the first time an integrated hierarchically organized molecular based observation strategy as a valuable tool to survey phytoplankton abundance and biodiversity in the desired high spatial and temporal resolution as well as at different levels of taxonomic resolution. The observation strategy is based on a combination of ship based automated filtration, online measurements of oceanographic parameter, and different molecular analyses. On one hand, our approach provides near real time information on phytoplankton key species abundance in relation to environmental conditions already on board ship. On the other hand, it provides detailed information on variability in the total phytoplankton community composition based on comprehensive, laboratory-based molecular analyses such as molecular fingerprinting methods and NGS. This information can be subsequently correlated with information on the physical and chemical marine environment and has strong

Manuscript under review for journal Ocean Sci.
Published: 23 May 2016

potential to complement other hierarchically organized observation strategies as described e.g. for the detection of marine hazardous substances and organisms (Zielinski et al., 2009). In summary, our molecular observation strategy is a significant contribution to refine regular assessment of consequences of ongoing environmental change for marine phytoplankton communities with respect to adequate spatial, temporal, and taxonomic resolution.

5 Acknowledgements

This work was supported through the Coastal Observing System for Northern and Arctic Seas (COSYNA), by institutional funds of the Alfred Wegener Institute for Polar- and Marine Research, Bremerhaven, funds of the Helmholtz Zentrum Geesthacht Centre for Materials and Coastal Research, and funds of the Initiative and Networking Fund of the Helmholtz Association for financing the Helmholtz-University Young Investigators Group PLANKTOSENS (VH-NG-500). We thank the crew of R.V. *Polarstern* for excellent support during the work at sea. Furthermore we thank Kerstin Oetjen, Swantje Rogge and Christiane Lorenzen for great technical assistance. Annegret Müller and Uwe John are acknowledged for excellent technical support of the fragment analysis.
