9

## 10 Abstract

11 Genealogical Evolution Model (GEM) is an efficient logical model used to track dynamic evolution of mesoscale  
12 eddies in the ocean. It can distinguish different dynamic processes (e.g., merging and splitting) within a dynamic  
13 evolution pattern, which is difficult to accomplish using other tracking methods. To this end, GEM first uses a two-  
14 dimensional (2-D) vector rather than a scalar to measure the similarity between eddies, which effectively solves the  
15 “missing eddy” problem (temporally lost eddy in tracking). Second, GEM uses both parents and children in tracking,  
16 and the dynamic processes are described as birth and death of different generations. Additionally, a look-ahead  
17 approach with selection rules effectively simplifies computation and recording. All of the computational steps are  
18 linear and do not include iteration. Given the pixel number of the target region  $L$ , the maximum number of eddies  $M$ ,  
19 the look-ahead time steps  $N$ , and the total number of time steps  $T$ , the total computation complexity is  $O$   
20  $(LM(N+1)T)$ . The tracking of each eddy is very smooth because we require that the snapshots of each eddy on  
21 adjacent days overlap one another.

22 Although eddy splitting or merging is ubiquitous in the ocean, there were related different distribution patterns when  
23 we applied GEM to track eddies in the Northern Pacific Ocean. Both the merging and splitting rates of the eddies  
24 were high, especially at the western boundary, in currents and in “eddy deserts.” GEM is useful not only for  
25 satellite-based observational data but also for numerical simulation outputs. It is potentially useful for studying  
26 dynamic processes in other related fields, e.g., the dynamics of cyclones in meteorology.

27

## 28 1 Introduction

29 Eddies are ubiquitous in the ocean, and they move from one place to another [Chelton and Schlax, 1996; Chelton et  
30 al., 2007]. Eddies in the ocean can cause large-scale transports of heat, salt and other passive tracers [Bennett and

31 White, 1986; Chelton et al., 2011a; Dong et al., 2014; McGillicuddy et al., 2011] by trapping these passive tracers  
32 inside the eddies. Such transports has important impacts on the environment and climate of the ocean [Dong et al.,  
33 2014]. To address various applications in the studies that use satellite products of sea level anomaly (SLA) data [e.g.,  
34 Chelton et al., 2011b] and numerical simulation outputs [e.g., Petersen et al., 2013], oceanic eddies should be  
35 automatically recorded using these data and outputs [e.g., Yang et al., 2013; Sun et al., 2014; Pegliasco et al., 2015].  
36 In general, the recording of oceanic eddies often includes two independent steps: automated eddy identification and  
37 automated eddy tracking. The eddies are identified in a sequence of SLA maps using an identification algorithm. An  
38 automated tracking procedure is then applied to determine the trajectory of each eddy [Chelton et al., 2011b].  
39 Recently, several automated identification and tracking algorithms have been developed for eddies in the ocean  
40 [Chelton et al., 2011b; Ienna et al., 2014; Mason et al., 2014; Yi et al., 2015].

41 For the eddy tracking stage, according to a recent census [Wang et al., 2015; Yi et al., 2015], approximately 10-30%  
42 of eddies may be found in proximity to a neighboring eddy in any given global SLA map. Therefore, an eddy  
43 tracking process should have the capability to distinguish different dynamic processes (e.g., merging and splitting)  
44 during its dynamic evolution. Moreover, an eddy tracking process must be accurate and fast enough to handle a huge  
45 amount of data, which will be even larger in size if spatio-temporal resolution of observations and numerical  
46 simulations increases.

47 Various implemented automated tracking procedures differ in detail, but they are all similar in concept because they  
48 utilize the closest eddy strategy [Chelton et al., 2011b]. For each eddy  $E_i$  identified at time step  $k$ , the closest eddy to  
49  $E_i$  at the next time step  $k+1$  is identified as part of the trajectory of eddy  $E_i$ . A more advanced procedure uses eddy  
50 shape error as an additional condition when searching for an eddy trajectory [Mason et al., 2014].

51 However, there is a “missing eddy” problem that must be solved in the eddy tracking stage [Chelton et al., 2011b].  
52 An eddy at time step  $k$  may have no associated eddy at time step  $k+1$ , which is simply due to a temporary missing  
53 eddy in the identification process; this can occur for a variety of reasons related to sampling errors and measurement  
54 noises [Chelton et al., 2011b]. Chelton and his colleagues made an attempt to accommodate such problems; they  
55 allowed for the reappearance of a temporarily missing eddy by looking ahead two or three time steps. Unfortunately,  
56 this “look-ahead” procedure considers too many nearby eddies as potential ones. In practice, the results of this  
57 simple “look-ahead” procedure were disappointing because the resulting eddy trajectory often jumped from one  
58 eddy to another. As a result, it was abandoned, even though this look-ahead feature is highly desirable [Chelton et al.,  
59 2011b].

60 Recently, the concept of multiple hypothesis assignment (MHA) was introduced to solve the missing eddy problem  
61 by abandoning the simple closest eddy strategy and applying a new “look-ahead” procedure [Faghmous et al., 2013].  
62 The MHA method can effectively solve the missing eddy problem in a straight line model when the following  
63 trajectory being followed is a branch without any splitting, but it is algorithmically and computationally complex.  
64 Given the maximum number of eddies in any time frame  $M$ , the number of look-ahead time steps  $N$  (with  $N=0$  being

65 the original linear closest eddy procedure without look-ahead) and the total number of time steps  $T$ , the MHA has a  
66 larger computational complexity,  $O(M^{N+1}T)$  [Faghmous et al., 2013].

67 The existing straight-line model can trace the kinematic motion of eddy. The dynamic evolutionary processes (e.g.,  
68 merging and splitting) of the eddy are, however, ignored by the model. This implies that each eddy  $E_i$  identified at  
69 time step  $k$  has only one eddy as part of its trajectory at time step  $k-1$  and has only one eddy as part of its trajectory  
70 at time step  $k+1$ . In the ocean, small eddies may merge to form larger ones. As shown in Figure 1, the anticyclonic  
71 eddies AC1 and AC2 observed on July 26, 2006 merged into a single one on July 31, 2006. Then, the cyclonic  
72 eddies C1 and C2 on July 26, 2006 merged to form a larger one on August 3, 2006. To describe such processes, the  
73 eddy tracking records should be trees with branches instead of simple straight lines.

74 To record the dynamic evolution of eddies, two fundamental algorithms are required. First, the two nearby eddies  
75 should be distinguished in the identification stage using a segmentation strategy in which the target region is divided  
76 into two corresponding eddies. Otherwise, the merging and splitting processes cannot be determined properly. This  
77 problem was recently solved by the use of segmentation strategies, e.g., the close-distance segmentation strategy [Li  
78 et al., 2014] and the watershed strategy [Li and Sun, 2015]. Because these segmentation strategies can distinguish  
79 closed eddies, they can also potentially reduce the risk of having a missing eddy in the identification process.

80 Second, the merging and splitting processes in the tracking stage should be described in details. We use a multi-  
81 branch tree model to do so. The eddy  $E_i$  identified at time step  $k$  may be more than one eddy at time step  $k-1$ , which  
82 are merged; and it may become more than one eddy at time step  $k+1$ . We refer to this model as the “Genealogical  
83 Evolution Model (GEM)” because it is a genealogical tree for recording the whole evolutionary history of an eddy.  
84 The multi-way tree model in computer science can be used to store this type of structure.

85 Moreover, the GEM also provides a new way to solve the missing eddy problem. Instead of the existing closest eddy  
86 strategy, a temporal track tree with  $N$  look-ahead time steps is used to maintain all possible tracks with the help of  
87 the multi-way tree model. The method can effectively solve the missing eddy problem, regardless of whether the  
88 eddy is splitting or not.

89 In this paper, we introduce the GEM to describe mesoscale eddies in a tracking process with a total number of time  
90 steps  $T$ . The GEM allows the eddy to have multiple eddies as its parents or as its daughters in a multi-branch model.  
91 It also solves the missing eddy problem by using a new look-ahead method similar to the MHA. Compared with the  
92 computational complexity  $O(M^{N+1}T)$  of MHA, the new method is much faster and has much less computational  
93 complexity  $O(LM(N+1)T)$ , where  $L$  the pixels of target region. If the algorithms work well, the output data will  
94 record the dynamic evolution of the eddy in detail and will potentially be useful for other research field, e.g., the  
95 dynamics of cyclones in meteorology. The GEM is applied to eddies in the North Pacific Ocean (NPO) only, to limit  
96 the size of the study area, and we assume the eddies do not cross the equator.

97 The paper is organized as follows. The data and eddy detection method used in this study are introduced in section 2.  
98 Then GEM is introduced in section 3, including similarity vector, look-ahead approach and the computation  
99 complex. Results including eddy tracks and examples of merging and splitting events are illuminated in section 4.

100 The impacts of data noises and parameters on the results are discussed in section 5. Finally, a summary and  
101 conclusions are given in section 6.

102

## 103 **2 Eddy detection**

### 104 **2.1 Input data**

105 The input data mainly include the original flow field, which can come from satellite observations or numerical  
106 simulations. The flow field used in this study is the 20-year (1993-2012) *daily* SLA data from the merged and  
107 gridded satellite product of Maps of Sea Level Anomaly (MSLA) at  $0.25^\circ \times 0.25^\circ$  resolution in the global ocean by  
108 the AVISO (<http://www.aviso.oceanobs.com/>). The data were corrected for all geophysical errors by the data  
109 provider. In this study, we use the “DT14” (delayed-time 2014) altimeter product [Duacs/AVISO, 2014], which is  
110 adequate for direct eddy detection [Capet et al., 2014] though it still has about 2-3 cm error globally for short  
111 temporal scales [Carrere et al., 2016]. A comprehensive discussion of gridded products for eddy investigations can  
112 be found in Chelton et al. (2011b).

113 We used the original SLA data (“DT14”) without any filtering or smoothing to identify eddies in this study.  
114 However, this does not imply that data smoothing is not needed for the SLA data in related studies. For example,  
115 to calculate some eddy parameters (e.g., velocity and vorticity), some kind of smoothing is required to remove data  
116 errors, as pointed out by Chelton et al. (2011b). Moreover, the data errors, even if they are very small, might affect  
117 eddy detection (see discussion in section 5.1).

### 118 **2.2 Eddy identification**

119 The eddy identification used in this study is similar to those used before [Chelton et al., 2011b; Mason et al., 2014],  
120 to identify eddies in the SLA data. The following mononuclear eddy definition is also similar to what was used by  
121 other authors [Chaigneau et al., 2011; Li et al., 2014; Li and Sun, 2015]. Each pixel has eight nearest neighbours. A  
122 point within the region is a local extremum if it has an SLA greater or less than all of its nearest neighbours. We also  
123 use such definition of extremum in our following analysis, in which the extrema are identified by checking each  
124 pixel in the map along with the eight pixels around it. An eddy is defined as a simply-connected set of pixels that  
125 satisfies the following criteria:

- 126 (1) only *one* SLA extremum exists in the pixel set;
- 127 (2) the SLA value of the eddy is above (below) a given SLA threshold;
- 128 (3) the amplitude of the eddy (the max difference of SLA values) is larger than a critical value (e.g., 1 cm);
- 129 (4) the area of the eddy must be large enough (say >16 pixels).

130 Conditions (2)-(4) provide the lower bounds for eddy size and amplitude. These conditions automatically reduce the  
131 total number of detected eddies, especially for the small ones. Condition (2) is the same as the first criteria in  
132 Chelton et al., (2011b). It is used in consideration of the 2-3 cm of background SLA error [Carrere et al., 2016]; so,  
133 small fluctuations in SLA field would not be taken as eddies in this study. Condition (3) was generally used  
134 previously [Chaigneau et al., 2011; Chelton et al. 2011]. Condition (4) is more restrictive than the generally used  
135 value of eight pixels [e.g., Chelton et al., 2011; Li et al., 2014]; so, this condition is an add-on, which is potentially  
136 useful when deriving eddy parameters using a nonlinear optimal fitting method [Wang et al., 2015; Yi et al., 2015].  
137 If the eddy area is too small (only a few pixels), its parameters are very sensitive to its area (number of pixels). The  
138 above criteria also remove the constraints of eddy pixel number maximum (e.g., <1000) and eddy size (e.g., <400-  
139 1200 km) [e.g., Chelton et al. 2011; Mason et al., 2014]. So, they are simpler and more consistent.

140 The SLA extremum so determined is called eddy center. The set of pixels belonging to an individual eddy is referred  
141 to the territory of the eddy, and the outmost SLA contour is the boundary of the eddy. We use the territory and  
142 boundary to calculate the similarity of eddies in section 3.2.

### 143 2.3 Necessity of segmentation

144 Figure 2 illustrates the necessity for eddy segmentation using the merging process of two eddies. Two different  
145 mononuclear algorithms are used in the upper and lower rows. In the top panels of Figure 2, eddies are identified by  
146 non-segmentation algorithm. Such mononuclear eddies may be very small. The time evolutions from  $t=1$  to  $t=3$   
147 show a decay scenario of two closed eddies C1 and C2. Both their amplitudes and areas become smaller and smaller  
148 with time. Then, a large eddy C3 suddenly appears in the same region without any premonition. It is hard to see  
149 what happened during the time from  $t=1$  to  $t=3$  from the above-identified eddy parameters. In contrast, the bottom  
150 panels of Figure 2 show a merging scenario of two closed eddies C1 and C2 using the segmentation algorithm [Li  
151 and Sun, 2015]. During the time from  $t=1$  to  $t=2$ , both their amplitudes and areas are seldom changed, while their  
152 distance is continually shortened. Then, a large eddy C3 naturally emerges in the same region, while C1 and C2  
153 disappear. It is recognized from the eddy data that C3 is the merging result of C1 and C2.

### 154 2.4 Eddy segmentation

155 Each eddy is identified by the following procedures. First, we find a simply-connected region with a given threshold.  
156 Second, we check whether there is at least one extremum in the region. Third, we check whether the region satisfies  
157 the eddy conditions (2) and (3). Finally, we check whether the eddy is multinuclear. Since both (2) and (3) allow the  
158 eddy to be multinuclear, we explicitly add condition (1) as a constraint. However, we need a segmentation method to  
159 implement this.

160 Figure 3 illustrates this eddy segmentation strategy. Figure 3a shows two individual but nearby eddies. The pixels  
161 between the two dashed lines are naturally divided by the watershed. As shown in Fig. 3b, the cross section of the  
162 eddy clearly shows that two closely located particles  $P_1$  and  $P_2$  on the left and right sides of watershed slide along

163 their ways to different eddy centres. The shape of SLA can provide sufficient information to segment the  
164 multinuclear eddy into mononuclear ones.

165 Herein, we use the Mononuclear Eddy Identification (MEI) of the Universal Splitting Technology for Circulations  
166 (USTC) with watershed segmentation [Li and Sun, 2015] to produce eddy parameters, including amplitude, radius,  
167 territory, and boundary (Fig. 3), which might be potentially used in other studies [Sun et al., 2014].

168 The GEM mainly represents the logical relationship of eddies, which is less dependent on physical parameters. To  
169 this end, the GEM takes the previously-identified eddies by MEI (with territory/boundary, see section 2.2) as its  
170 input data.

171

## 172 **3 Dynamic tracking**

### 173 **3.1 Overview of GEM**

174 The GEM is a logical model used for tracking the dynamic evolution of mesoscale eddies in the ocean (Fig. 4). The  
175 model essentially establishes logical relationships of previously-identified eddies. The relationships are determined  
176 by two relatively independent steps: first, measuring the “map link,” and then connecting to the “track tree.”

177 The first part of GEM is “map link,” which uses input eddy data (with territory/boundary, see section 2.2) to  
178 establish the link between eddies in different snapshots. In this part, we use a 2-D vector rather than a passive scalar  
179 to measure the similarity between eddies  $E_1$  and  $E_2$  on two neighboring days (Figs. 5 and 6, see section 3.2 for  
180 details). We then use a relatively complex look-ahead procedure to solve the missing eddy problem (section 3.3).  
181 This new look-ahead approach has a duration of  $N$  days (Fig. 7). Finally, the links between the eddies in different  
182 snapshots are saved (see section 3.3 for details).

183 The second part is “track tree,” which uses the outputs from “map link” (i.e., eddy links), as its input (Fig. 4). It  
184 connects the eddy links from branches to a tree with the genealogical model (Fig. 8) using two sub procedures:  
185 “eddy branch” and “eddy tree.” In the “eddy branch” part, we use *parent* and *child* to define the eddy relationship  
186 and define all possible types of eddy states: birth, death, living, missing, merging and splitting (Fig. 8a).  
187 Consequently, we identify different roles in the eddy branches (see section 3.4 for details). Finally, in the “eddy  
188 tree” procedure, we connect the branches based on their roles in the genealogical tree (Fig. 8b). The output of GEM  
189 includes eddy tracks and the records of eddy relationships (see section 3.5 for details).

190 In short, the GEM uses previously-identified eddies and/or their links to make dynamic tracks via a genealogical tree  
191 model. In addition, it includes two parameters, the critical value of area ratio  $r_c$  and  $N$ , as inputs. See section 5.2 for  
192 discussion on the impacts of these parameter choices.

### 193 3.2 Similarity vector

194 To establish the connection of the previously-identified eddies, the first part of GEM evaluates the similarity of  
 195 these eddies. As shown in Figure 5a, there were eddies A1, A2 and B1 detected on March 28, 1997. In Figure 5b,  
 196 there were four eddies, A1, A2, B1, and B2 on March 29, 1997. We overlapped the eddy territories into a single map  
 197 (Fig. 5c). Then, we used the intersection of eddy territories on different days to calculate the similarity. For eddies  
 198 A1 and A2, the intersection was very close to both territories on the first day, and on the second day. For eddy B1,  
 199 the intersection was close to the territory on the second day, but it was only part of that on the first day.  
 200 Consequently, eddies A1 and A2 had full similarity on these days, while eddies B1 and B2 only had partial  
 201 similarity on these days.

202 To estimate the above similarity, let us describe it in a logical way. As shown in Figure 6a, there is an eddy ( $E_1$ ) that  
 203 is identified by the thick contour of Boundary 1 in the rectangular comparison region on days 0, and there are three  
 204 eddies ( $E_2$ ,  $E_3$  and  $E_4$ ) that are identified in the same region on day 1. This comparison region, which is centered at  
 205 the eddy center of  $E_1$ , moves in time with the target eddy ( $E_1$ ). To determine the similarities between  $E_1$  on day 0 and  
 206  $E_2$  to  $E_4$  on day 1, we overlap the eddy territories into a single map. For example, to determine the similarity  
 207 between  $E_1$  and  $E_2$ , we count the overlap area  $S_{12}$  (defined as the intersection of Boundary 1 and Boundary 2)  
 208 between  $E_1$  (area  $S_1$ ) and  $E_2$  (area  $S_2$ ), and then we calculate the following ratios:

$$209 \quad r_1 = S_{12} / S_1, \quad (1a)$$

$$210 \quad r_2 = S_{12} / S_2. \quad (1b)$$

211 Clearly, the values of  $r_1$  and  $r_2$  are within [0,1]. The larger  $r_1$  and  $r_2$  are, the larger possibility  $E_2$  has to be the  
 212 snapshot of  $E_1$  on day 1. Eddy movement speeds are generally less than 0.1 m/s, which implies that an eddy can only  
 213 move one grid ( $0.25^\circ$ ) in 3-4 days. Thus, the overlap of the same eddy territory should be large enough. We choose  
 214  $r_c=2/3$  for this study, and the choice of  $r_c$  is comprehensively addressed in section 5.2.

215 Using the vector  $(r_1, r_2)$  and the critical value  $r_c$ , we define four different types of similarity between two eddies (Fig.  
 216 6b). From low to high, they are as follows: Type 0 (T0), where  $E_1$  and  $E_2$  are unrelated; Type 1 (T1), where  $E_1$  on  
 217 day 0 is part of  $E_2$  on day 1 ( $E_1$  enlarging or merging); Type 2 (T2), where  $E_2$  on day 1 is part of  $E_1$  on day 0 ( $E_1$   
 218 decaying or splitting); and Type 3 (T3), where  $E_1$  and  $E_2$  are the same eddy at different locations on different days  
 219 ( $E_1$  living and moving). The last type (T3) can also be identified in cases when the center of  $E_1$  propagates less than  
 220 a pixel toward that of  $E_2$ , because the eddy movement speed is physically less than one grid ( $0.25^\circ$ ) per day. For  
 221 example, eddy B1 on March 29, 1997 in Figure 5b is simply assigned to T3 even though  $r_1 < r_c$ . Eventually, we  
 222 obtain the relationships between  $E_1$  and  $E_3$  or  $E_4$  (Fig. 6a). Because the present method uses a vector to express eddy  
 223 similarity, we call it the similarity vector. This is an alternative way for dimensionless similarity parameters [e.g.,  
 224 Ienna et al., 2014; Mason et al., 2014].

225 For example, as shown in Figure 6a, the good similarity between  $E_1$  and  $E_2$  over a critical value  $r_c$  (marked as T3 in  
 226 Fig. 6b) suggests a connection from  $E_1$  to  $E_2$ . Eventually, the “eddy branch” procedure (in section 3.4) establishes an

227 inheritance connection in Figure 6a according to the branch definition in Figure 8a. This is similar for eddies  $E_1$  and  
228  $E_3$ , but with a different splitting relationship (marked as T2 in Fig. 6b). However, the relationship between eddies  $E_1$   
229 and  $E_4$  is designated as “unrelated” because of the overlap in their territories is small or zero. In other words, their  
230 overlap rates are below the critical value  $r_c$  (marked as T0 in Fig. 6).

231 In previous eddy tracking studies, simple methods were used for weekly SLA data (delayed-time 2010), e.g., the  
232 closest distance between eddies [Chelton et al., 2011b; Yi et al., 2015], the closest direction between eddies [Zhang  
233 et al., 2014] and the dimensionless similarity scalar [Chaigneau et al., 2008; Mason et al., 2014]. There is always a  
234 risk of eddy jumping (from one track to another) in these methods, except for that of Pegliasco et al. (2015), who  
235 used intersections of eddy boundaries to find the continuing eddy. Compared to the previous tracking methods, we  
236 use a more robust technique to measure neighboring eddies by using the overlap in their territories. In addition, we  
237 do not simply assign the continuing eddy using the similarity vector for the two adjacent days; rather, we try to solve  
238 the temporary missing eddy problem by looking ahead a few days.

### 239 3.3 Look-ahead

240 In contrast to the procedure used in Chelton et al. (2011b), we use a relatively complex look-ahead procedure. Some  
241 possibilities for a given eddy are shown in Figure 7a. In the upper row, both  $E_1$  and  $E_2$  take the same eddy  $E_3$  as  
242 their subsequent T1 type of eddy, which is a merging event (e.g., eddies C1 and C2 in Fig. 1). Since a T1 eddy has  
243  $r_2 < r_c$  (intersection only takes a part of the eddy on day 1), two or more eddies (e.g.,  $E_{c1}$  and  $E_{c2}$ ) on day 0 could  
244 identify the same eddy ( $E_{c3}$ ) as T1 eddy simultaneously on day 1. In the middle row, eddy  $E_1$  has two T2 type of  
245 eddies ( $E_{c2}$ ,  $E_{c3}$ ) at the same time; this is a splitting event (e.g., eddies B1 and B2 in Fig. 5). In the lower row, eddy  
246  $E_1$  has T2 and T3 types of eddies (respectively  $E_{c2}$ ,  $E_{c3}$ ) at the same time. Although there may be many  
247 possibilities for any given eddy, there is at most one eddy that can be marked as a T1 or T3 eddy on the following  
248 day (as  $r_j > r_c$  holds).

249 This new look-ahead approach with  $N$  daily is shown in Figure 7b. After finishing the calculation of the following  
250 eddies on day 1, we continue to calculate eddies on the following days. At this preparation stage, it is similar but  
251 slightly different than the MHA method [Faghmous et al., 2013]. What makes this look-ahead procedure novel and  
252 efficient is that we use two simple rules to directly choose only one day’s result for the following eddies. Thus, the  
253 procedure becomes linear without iteration, and it is much faster than the MHA, as discussed in the subsection on  
254 the computation complexity (section 3.6).

255 The two selection rules are: 1) the most similar first, and 2) the closest day first. Rule 1 has priority. We first choose  
256 the most similar eddy as the potential one according to their types. According to Figure 6b, T2 type eddy covers  
257 only part of the original eddy while T1 eddy covers most part of the original eddy. The similarity from low to high is  
258  $T2 < T1 < T3$ . For example, if there is only one T3 eddy in these days, we choose it as the potential one. However, if  
259 there is more than one day with the same type of eddies, we need an additional rule: the closest day first. For  
260 example, in the upper row of Figure 7b, there is one T3 eddy on day 1, there is one T3 eddy on day 2, and there are

261 two T2 eddies on day 3. In this case, we choose day 1 as the following day and the T3 eddy as the following E1. In  
262 the middle and the lower rows, we choose day 2 and day 3 as the following days and the corresponding T3 eddies as  
263 the following E1.

### 264 3.4 Eddy branch

265 After having determined the look-ahead day and the following eddy types based on the above process, we can now  
266 establish the branches of an eddy from one day to the next. To describe the GEM more precisely, we use *parent* and  
267 *child* to identify the different roles that the eddy plays in eddy branches. There are three types of logical  
268 relationships used in GEM, as shown in Figure 8a.

269 The upper row shows a successor relationship: an eddy P on day 1 has only one successor (eddy P itself) on day 2.  
270 In this case, eddy P is allowed to be missing during day 1 and day 2. Additionally, eddy P will be recorded as death  
271 (black circle), if no successor eddy is found after  $N$  days.

272 In the middle row, two (or more) eddies merge into one. The first type includes principal and subordinate merging.  
273 A principal eddy  $P_1$  and a subordinate eddy  $P_2$  on day 1 merge into a larger eddy  $P_1$  on day 2, whereas  $P_2$  is recorded  
274 as death. This occurs when a large eddy meets and merges with a small eddy (e.g., C1 and C2 in Fig. 1). The  
275 anticyclonic eddies A1 and A2 in Fig. 11 also experience a similar process (see section 4.2 for details). The second  
276 type is coordinated merging. Two (or more) parent eddies  $P_1$  and  $P_2$  merge to produce a new child eddy C, and all of  
277 the parent eddies are recorded as death. This is because we could not decide to which of  $P_1$  or  $P_2$  the record of eddy  
278 C should be appended. There might be another choice by keeping parent eddies  $P_1$  and  $P_2$  alive and appending the  
279 record of eddy C to both eddies. This choice artificially increases total records and leads to other tracking problems;  
280 so, we simply abandon it.

281 In the lower row, a parent eddy splits into several child eddies. The first type is principal and subordinate splitting. A  
282 parent eddy P splits into an eddy P (itself) and a child eddy C, which is recorded as birth. The second type is  
283 coordinated splitting. Two (or more) child eddies are born from the parent eddy P, which is then recorded as death.

### 284 3.5 Track tree

285 Finally, the track tree is recorded by connecting the eddy branches (Fig. 8b). In this process, the role that an eddy  
286 plays in the track tree should be considered. The first generation is the parent eddy (e.g.,  $P_1$ ), the second generation  
287 is the child eddy (e.g.,  $C_1$ ) and the third generation is the grandchild eddy (e.g.,  $G_1$ ). The track tree basically uses the  
288 above eddy branches (Fig. 8a). We connect the branches from one time to another to obtain the whole eddy track  
289 tree.

290 There are two additional notations. First, an eddy emerging from the same family of eddies (e.g., two siblings  $C_2$  and  
291  $C_4$ ) will be recorded as a new family member (e.g., eddy  $C_5$ ). Second, an eddy merging from two different families  
292 of eddies (e.g.,  $C_1$  and  $P_2$ ) will be recorded as a new eddy  $N_1$ .

293 Although the model could have several generations, we only recorded two generations in this study due to the  
294 complexity of the output data structure. However, we can indirectly track other generations using the relationships  
295 between them.

### 296 3.6 Computation complexity

297 To calculate similarity vectors, we need to overlap two small regions around eddy E1. The total number of pixels in  
298 the rectangular comparison region is  $L$ . The computational complexity of the similarity vector is  $O(L)$  for each day.  
299 If we use  $N$  look-ahead time steps to find the best choice, the computation complexity of the branches will be  $O$   
300  $(L(N+1))$  for one eddy. Because all of the steps are linear without iteration, given the maximum number of eddies in  
301 any time frame  $M$ , the number of look-ahead time steps  $N$  and the total number of time steps  $T$ , the total computation  
302 complexity is  $O(LM(N+1)T)$ . This might be the fastest method possible. When the number of look-ahead time steps  
303  $N$  is more than one, the computation complexity is much faster than  $O(M^{N+1}T)$  of MHA.

304 For example, both  $L$  and  $M$  are approximately 1000, and  $N=2$  is used in the present study. The MHA method will  
305 require on the order of  $10^2$ - $10^3$  times more computational time than the present method; and the larger the value of  $N$ ,  
306 the more efficient the present method is. The look-ahead time  $N$  may be potentially as large as one week ( $N=6$ ), as  
307 noted in the following discussion. Thus, the present method is especially effective when a long look-ahead time is  
308 required for poorly identified eddies.

309

## 310 4 Results

### 311 4.1 Eddy tracks

312 We first apply the MEI to detect the ocean eddies in the North Pacific Ocean (NPO) during 1993-2012. The eddy  
313 centers (SLA extrema of eddy snapshots) on each day are counted on each  $1^\circ \times 1^\circ$  grid. In general, anticyclonic eddies  
314 are significantly more than cyclonic eddies. As shown in Figure 9a, the cyclonic eddies are mainly located in the  
315 western part of the NPO. For example, there are lots of cyclonic eddies east of Japan near the Kuroshio, which can  
316 also be seen from both Figure 1 and the results in section 5.1. In contrast, anticyclonic eddies are mainly located in  
317 the eastern part of the NPO (Fig. 9b). For example, the eddies are mainly anticyclones in the red box, which can also  
318 be seen from the results in section 4.2. In general, the eddies are ubiquitous in Figure 9c (about 50-70 eddies per  
319 year on each  $1^\circ \times 1^\circ$  grid), except that there are several regions where both types of eddies are relatively scarce. One  
320 of them is known as “eddy desert” [Chelton et al., 2007]. The other region is the North Equatorial Countercurrent  
321 (NECC) [Hu et al., 2015]. Finally, we present in Figure 9d the ratio of difference in number of cyclonic and  
322 anticyclonic eddies to the total number of eddies.

323 We apply the GEM to these eddies detected by MEI with  $r_c=2/3$  and  $N=2$ . In the NPO, there are a total of 60276  
324 eddies with lifetimes longer than 30 days. Among them, 37553 of the eddies are anticyclonic and 22723 are cyclonic.  
325 The tracks of long-lived eddies are plotted in Figure 10. In general, they are similar to those shown in previous

326 studies [Chelton et al., 2011b]. There are 7290 anticyclonic and 3627 cyclonic eddies with lifetimes longer than 100  
327 days (Fig. 10a), and the ratio of anticyclonic to cyclonic eddies is approximately 2. The ratio is larger for eddy  
328 lifetimes greater than 400 days, which was also noted in previous studies [Chelton et al., 2011b; Xu et al., 2011].  
329 Each track is very smooth because we require that the snapshots of eddies on different days overlap one another.  
330 The long-lifetime eddy trajectories imply that the quality of the tracking results is reasonable. We will take the long-  
331 life C1 in Figure 10b as an example.

332 Eddy C1 was first detected as an eddy initiated on September 14, 1995, with an extremum at 163.5°W, 10.5°N. It  
333 then travelled to the northwest and disappeared at 151.25°W, 20.5°N on March 11, 1997. Its trajectory is the longest  
334 that we have detected in the NPO (Fig. 10b). The trajectory is smooth, except for a sudden jump from 167.5°E to  
335 166.75°E (Fig. 10c) on July 31, 1996. Therefore, a puzzle emerged regarding whether we should connect the  
336 trajectories from before July 30, 1996 with that after July 31, 1996, into a single trajectory.

337 To clarify this, we plot the two SLA fields in Figure 10d. The SLA field on July 30, 1996 is plotted as contours. The  
338 eddy center is marked by a black cross at 167.5°E, 16.5°N. In contrast, the SLA field on July 31, 1996 is plotted in  
339 shading. The eddy center is marked by a red cross at 166.75°E, 17.25°N. The distance between the eddy extrema was  
340 larger than 100 km within a day. Although that distance is far beyond the criterion in eddy tracking used in recent  
341 studies [Mason et al., 2014; Yi et al., 2015], we can see from the SLA fields that they both indicated the same eddy,  
342 and we should connect the trajectories into a single trajectory.

343 A similarity vector can effectively reduce the possibility of temporarily missing an eddy in tracking. In turn, it  
344 reduces the usage of the look-ahead procedure. It is clear that the similarity expressed as a vector is better than that  
345 as scale using simple distance.

#### 346 4.2 Eddy merging and splitting

347 The trajectories also provide evidence of dynamic evolution. The time evolution of a couple of anticyclonic eddies is  
348 depicted in Figure 11a, which implies a merging process occurring in the red boxes in Fig. 9. As shown in Figure  
349 11a, eddy A1 had a westward movement with a speed of 2.6 cm/s, and eddy A2 lingered near 133°W. Then, both  
350 eddies merged into one large eddy on April 23, 1997. That evolutionary process is clearly shown by the SLA fields  
351 (Figs. 11c-j). In Figure 11c, there were two anticyclonic eddies, A1 and A2, located at 132°W, 28.5°N. Eddy A1  
352 moved from east to west with a nearly constant speed of 2.6 cm/s, whereas eddy A2 had negligible zonal motion.  
353 They then rotated clockwise about each other with an average angular velocity of  $6 \times 10^{-7} \text{ s}^{-1}$ , as denoted by the blue  
354 arrows. Finally, they merged into the new large eddy A2.

355 The SLA field shows that an eddy splitting process also occurred. The time evolutions of anticyclonic eddies B1, B2  
356 and B3 are depicted in Figure 11b. At first, eddy B1 had a fast westward speed of 10.4 cm/s. It then split into two  
357 eddies (B1 and B2) on March 29, 1997 (Fig. 6). Eddy B1 traveled at its original speed whereas eddy B2 lingered at  
358 its origin. Then, eddy B3 emerged at a location between B1 and B2 on April 9, 1997, which slowed down the speed  
359 of B1 to approximately 3.5 cm/s. After that, eddies B2 and B3 merged into a new eddy B3 on April 19, 1997. In fact,

360 similar to eddies A1 and A2, eddies B1 and B2 eventually merged into a new eddy on May 20, 1997 (not shown).  
361 The SLA maps in Figures 11c-j show more details that were not recorded by the eddy tracking data. Note that eddy  
362 B2 had a very short lifetime of 20 days but a complex dynamic process. If only long-term eddies (lifetime > 30 days)  
363 were saved, the corresponding evolution process might not be recorded properly.

364 It is expected that cyclonic eddies will have a counter-clockwise rotation in the Northern Hemisphere, which is  
365 known as the Fujiwhara effect for cyclones [Fujiwhara, 1921]. When two cyclones are close enough, they will begin  
366 to orbit cyclonically (counter-clockwise in the Northern Hemisphere). Because the above-mentioned eddies are  
367 anticyclonic, they have opposing directions of rotation, which appear as two point vortices moving in circular paths  
368 about the center of vorticity in classical fluid dynamics [Batchelor, 1967].

### 369 **4.3 Census of merging and splitting events**

370 To illuminate how often the merging and splitting processes occurred, we counted the total number of merging and  
371 splitting events on each  $1^\circ \times 1^\circ$  grid each year. The merging and splitting events were ubiquitous in the oceans, but in  
372 general were very few times each year per  $1^\circ \times 1^\circ$  grid element. The merging frequencies for cyclonic eddies and  
373 anticyclonic eddies are shown in Figure 12, which are similar to their splitting frequencies (not shown). The  
374 distribution pattern of merging frequency for cyclonic eddies in Figure 12a, is very similar to that of cyclonic eddy  
375 centers in Figure 9a. In contrast, the merging frequency for anticyclonic eddies was larger along the west coast (Fig.  
376 12b), whereas the anticyclonic eddy centers were located mainly in the east (Fig. 9b). Although merging and  
377 splitting events may be ubiquitous in the ocean (Fig 12c,d), there are several types of special regions where merging  
378 and splitting events occur more frequently.

379 The first type of special region is the western boundary. It is known that the western boundary is a sink of eddy  
380 energy caused by the interaction with the bottom and lateral topography [Zhai et al., 2010]. It is also known as a  
381 “graveyard” for westward-propagating ocean eddies [Zhai et al., 2010; Chelton et al., 2011b]. The second type of  
382 special region is located in strong currents, including the Kuroshio Current, the North Equatorial Current (NEC) and  
383 the NECC [Hu et al., 2015]. Among those currents, the eddies in the NECC had the highest frequency of merging  
384 and splitting events, which was seldom noted in previous studies. The third type of special region is located in the  
385 northeast Pacific, which is also known as an “eddy desert” [Chelton et al., 2007]. The fourth type of special region is  
386 located in enclosed marginal seas, especially the Bering Sea.

387 By comparing Figure 12 with Figure 10, we can see that the regions with high frequencies of merging and splitting  
388 events have few eddy tracks, especially in the NECC and in the “eddy desert” in the northeast Pacific. The existence  
389 of “eddy desert” may be due to the fact that the eddy was too small to be detected or the fact that the eddy lifetime  
390 was too short [Chelton et al., 2011b]. However, Figures 9 and 12 suggest that fewer eddies accompanied by frequent  
391 dynamic (merging and splitting) events caused the “eddy desert.”

392

## 393 5 Discussion

### 394 5.1 Data noises

395 Although “DT14” is much better than previous products, there are still some notable errors, especially for short  
396 temporal scales of less than two months [Carrere et al., 2016]. It was reported that there are along-track SLA errors  
397 of about 2-3 cm globally and of more than 3 cm at high latitudes and in shallow waters.

398 To reduce the noises in SLA data, one may use the Gaussian structure filter [Chelton et al., 2011b; Mason et al.,  
399 2014], Hanning filters [Penven et al., 2005], or Lanczos filter [Chaigneau et al., 2008]. As some parameters are used  
400 in these filters, the filtered results depend much on these parameters [see Fig. A1 in Chelton et al., 2011b].  
401 Alternatively, we can simply use a five-point quadratic smoothing to remove the noises in SLA data. The filtered  
402 data are then piecewise  $C^2$ -smooth, which satisfies the potential requirements for calculating vorticity from SLA  
403 data.

404 Figure 13 shows the non-smoothed and smoothed SLA data from January 1, 1993 to January 4, 1993. The smoothed  
405 SLA maps are very close to the non-smoothed SLA maps. And the values at the SLA extrema are close to their  
406 original values. These imply that the noises in DT14 data are very small.

407 However, the noises cannot be neglected, even when they are small. They might induce false SLA extrema (see the  
408 definition of extremum in section 2.2), which eventually affect eddy detection, e.g., the false extremum on January 2,  
409 1993 in box A and the false extremum on January 3, 1993 in box B (Figure 13). These false extrema existed only for  
410 a very short period (one or two days). But they can induce false merging and splitting events, which may cause  
411 eddies to unexpectedly terminate [Chelton et al., 2011b]. This is one of the reasons why we need “look-ahead” in  
412 eddy tracking.

### 413 5.2 Impact of parameters

414 To discuss the impact of these parameters, we apply the GEM to the eddies detected in the NPO. There are two  
415 parameters in the GEM: the critical value  $r_c$  and the look-ahead time  $N$ . The numbers of eddies with lifetimes  $> 30$   
416 days are counted for different  $r_c$  and  $N$ , as shown in Figure 14a. Note that the results are very similar, except for  $N=0$   
417 (i.e., without any look-ahead). It is from the above discussion that we see look-ahead is necessary when there are  
418 extrema due to small noises in the data. The numbers of eddies seldom change with  $r_c$  for any  $N>1$ , when  $r_c$  is within  
419 0.5 to 0.8. Meanwhile, the numbers of merging and splitting events are also counted for different  $r_c$  and  $N$ , as shown  
420 in Figure 14b. In general, the splitting events are a little more than the merging events. Note also that the results are  
421 very similar, except for  $N=0$ . The numbers of merging and splitting events seem to converge for  $r_c > 0.5$  as  $N$   
422 increases. For each  $N>0$ , the numbers of merging and splitting events reach a maximum at  $r_c=0.6$ . A relatively loose  
423 similarity condition ( $r_c<0.5$ ) will lead to a risk of eddy jumping from one track to another, which consequently  
424 reduces both total eddy number and dynamic events. On the other hand, a relatively strict similarity condition  
425 ( $r_c>0.9$ ) will lead to a risk of missing eddies, which may also reduce both total eddy numbers and dynamic events.

426 In general, the tracking results should be insensitive to the choice of these parameters. From Figure 14, we can  
427 observe that  $0.5 < r_c < 0.8$  is a potential choice. The optimal value for  $r_c$  might be 0.6-0.7. We also find that the look-  
428 ahead time  $N$  should be larger than 0; otherwise, the risks of eddy jumping and eddy missing are too great. The look-  
429 ahead approach effectively reduces such risks. For example,  $N=1$  and  $N=2$  have 95.5% and 98% of the total eddies  
430 for  $N=4$ , respectively. To reduce the missing eddies to 1%, the look-ahead time might be greater than six days. This  
431 is also the physical requirement of the representative period of the merged SLA data [Chelton et al., 2011b].  
432 Although  $N=4$  and  $N=6$  might be better,  $N=2$  produced a very similar result (~2% bias) and with a significantly  
433 lower computational cost. Our present parameters are reasonable for these regimes.

434 Besides, as noted in section 4.2, there are short-term eddies (lifetime < 30 days), which might to though complex  
435 evolution process. If only long-term eddies (lifetime > 30 days) were saved, the corresponding evolution process  
436 might not be recorded properly. This should be noted in further applications on eddy dynamics with satellite  
437 altimetry data.

### 438 5.3 Impact of eddy boundary

439 Eddy boundary is influenced by the identification method and corresponding criteria used. In general, the automated  
440 eddy detection algorithms are categorized into three types: 1) physical parameter-based algorithms, e.g., Okubo-  
441 Weiss (O-W) parameter [Isern-Fontanet et al., 2003; Chaigneau et al., 2008]; 2) flow geometry-based algorithms  
442 [Chaigneau et al., 2011; Chelton et al., 2011b; Wang et al., 2015]; and 3) hybrid methods, which involve physical  
443 parameters and flow geometry characteristics [Nencioli et al., 2010; Xiu et al., 2010; Dong et al., 2011; Yi et al.,  
444 2015]. For example, Yi et al. (2015) used the O-W parameter to identify eddy kernels and SLA contour geometries  
445 to identify eddy boundaries. Thus, it is difficult to directly compare the influences of eddy territory using different  
446 tracking algorithms.

447 We can, however, estimate the influence of eddy boundary using an indirect way. Because the eddy center is  
448 relatively robust, different identification methods mainly give different eddy boundaries. Consequently, the eddy  
449 area  $S$  is most sensitive to such an eddy territory. However, the area ratio reduces the sensitivity to the eddy area  $S$   
450 because both the overlap area  $S_{12}$  and the eddy area  $S$  change synchronously. Moreover, our tracking results  
451 fortunately are not very sensitive to  $r_c$  (or the eddy area  $S$ ), as noted in the above discussion. For example, the  
452 present results are based on a very strict identification method. If we modify the threshold of eddy amplitude from 1  
453 cm to 3 cm, the number of identified eddies will decline. However, the identification results for the long-lived eddies  
454 appear to be similar (Table 1).

### 455 5.4 Future research

456 The GEM is a flexible model that can easily work with other relevant programs, e.g., data filtering and smoothing  
457 algorithms [Chelton et al., 2011b; Ienna et al., 2014; Wang et al., 2014], other hybrid eddy detection algorithms [e.g.,  
458 Yi et al., 2015] and O-W parameter detection [e.g., Petersen et al., 2013], because the GEM requires a flow field and

459 previously-identified eddies to accomplish dynamic tracking. In addition, the similarity measurement can be  
460 replaced by similar methods [e.g., Pegliasco et al., 2015] when considering more complex conditions.

461 The GEM is a complex model. The output data include eddy tracks, relationships and previously-identified eddy  
462 parameters (e.g., amplitude and radius). These eddy parameters, which were directly obtained from the identification  
463 process, are useful for censuses [Chelton et al., 2011b]. However, they may not be sufficient for some applications.  
464 For example, eddy territory was required in our recent studies on typhoons and oceanic eddy interactions [Sun et al.,  
465 2010, 2012, 2014]. A better way to obtain these parameters might be to use a nonlinear fitting of the flow field  
466 [Wang et al., 2015; Yi et al., 2015] with appropriate models [e.g., Sun, 2011; Zhang et al., 2013].

467 Another future research direction may involve comparing different tracking datasets. Because there are several  
468 tracking datasets produced by various methods, it is useful to inter-compare them. This may improve both the  
469 tracking methods and the available datasets for further studies.

470 The GEM can be easily applied to larger datasets, even to 3-D numerical simulation outputs [Petersen et al., 2013;  
471 Woodring et al., 2016], because its computational time increases linearly as a function of the size of the dataset. The  
472 computation of the 20-year daily global SLA data only required a few hours on a personal computer. Such a model,  
473 accompanied by other (e.g., velocity-based, O-W-based) identification methods, can be used to analyze numerical  
474 simulation outputs.

475 The GEM opens a window to investigate eddy dynamics [Wang et al., 2015] and other applications [Sun et al.,  
476 2014]. As illuminated in Figure 11, the dynamic evolution of eddies is accompanied by abundant phenomena that  
477 might be identified using the GEM. The present study is only the beginning of such applications.

478

## 479 **6 Conclusions**

480 We have introduced the GEM for tracking dynamic evolution of mesoscale eddies in the ocean. Several novel  
481 approaches (e.g., vector similarity and look-ahead approach) were applied to deal with unsolved problems in  
482 tracking. All of the computational steps in GEM are linear and do not require iteration. Given the grid number of the  
483 target region  $L$ , the maximum number of eddies  $M$ , the number of look-ahead time steps  $N$ , and the total time steps  $T$ ,  
484 the total computational complexity is of  $O(LM(N+1)T)$ . We applied the GEM to the eddies in the NPO. Each eddy  
485 track was very smooth because we required that the snapshots of eddies on neighboring days overlap one another.  
486 Both merging and splitting rates of eddies were high, especially at the western boundary, in strong currents and in  
487 “eddy deserts.” The GEM is useful not only for satellite-based observation data but also for numerical simulation  
488 outputs. It potentially has many applications for studies of dynamic processes in related fields, e.g., the dynamics of  
489 cyclones in meteorology. The “MEI” and “GEM” computer codes will be provided on request after publication of  
490 this paper.

593 Table 1. The census of long-lived eddies, where “Amp” represents the amplitude threshold used in eddy detection;  
 594 and “C” and “AC,” respectively, represent cyclonic and anticyclonic eddies.

Amp	AC (>100 d)	C (>100 d)	AC (>400 d)	C (>400 d)
1 cm	7290	3627	198	22
3 cm	7118	3550	194	21

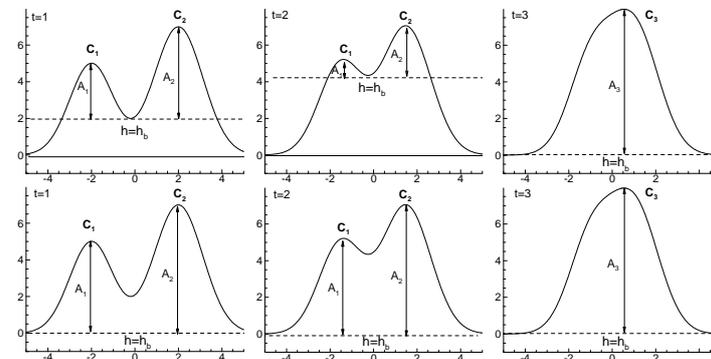

595

596

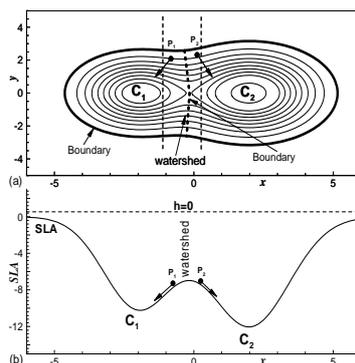

597 Figure 1. The evolutions of amplitudes and areas of eddies from July 5 to August 3, 2006 (after Li et al. 2014). Two  
 598 anticyclonic eddies AC1 and AC2 merged into a single eddy on July 31, 2006. And, two cyclonic eddies C1 and C2  
 599 merged into a single one on August 3, 2006.

600

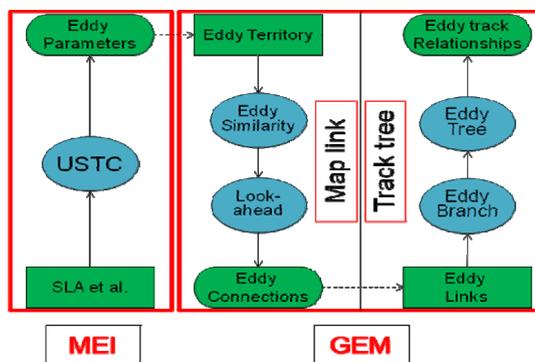

601

602 Figure 2. Top panels: Time evolution of two merging eddies revealed by the mononuclear eddy identification  
 603 without segmentation. Bottom panels: Time evolution of two merging eddies revealed by the mononuclear eddy  
 604 identification with segmentation.

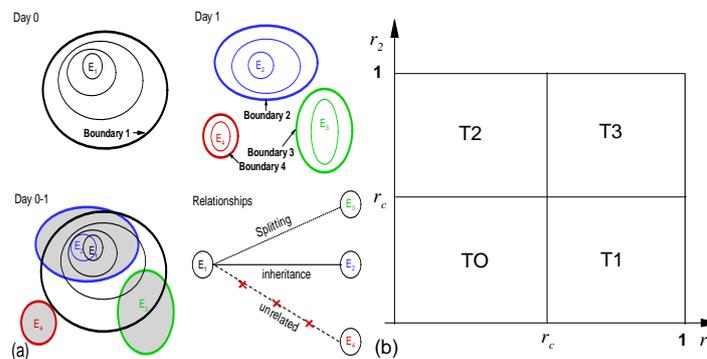

Figure 4. Flow chart of the systems. Mononuclear Eddy Identification (MEI) uses SLA to identify eddies via the Universal Splitting Technology for Circulations (USTC) method. The GEM, which has two independent parts of “Map link” and “Track tree,” then uses the previously-identified eddies for tracking.

614

615 Figure 5. Sketch of eddy overlaps. (a) The SLA map (shading) and the boundary of eddies (red curves) on March 28,  
 616 1997. (b) The SLA map (shading) and the boundary of eddies (blue curves) on March 29, 1997. (c) The intersection  
 617 of eddy territories by overlap eddy identification maps.

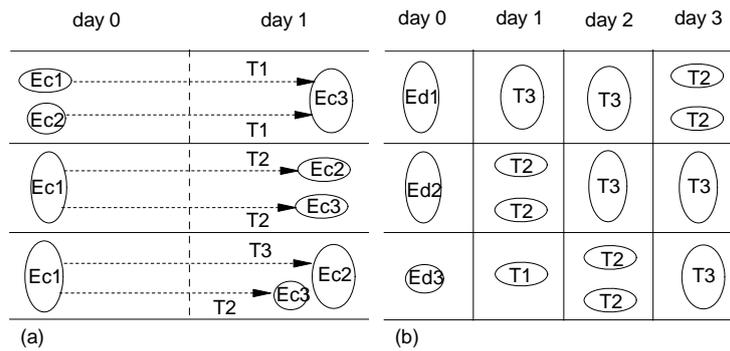

618

619

620 Figure 6. Sketch of eddy similarities. (a) The sketch of eddy overlaps. Eddy  $E_1$  (black) is the eddy identified on day  
 621 0, where the thin contours represent the eddy parameter (e.g., the SLA value). The thick contour represents the eddy  
 622 boundary. Eddies  $E_2$  (blue),  $E_3$  (green) and  $E_4$  (red) are identified on day 1. We consider the overlay between the two  
 623 eddies on different days to evaluate the similarity between them. (b) There are four types (T0-T3) according to the  
 624 values of  $r_1$ ,  $r_2$  and the critical value  $r_c$ .

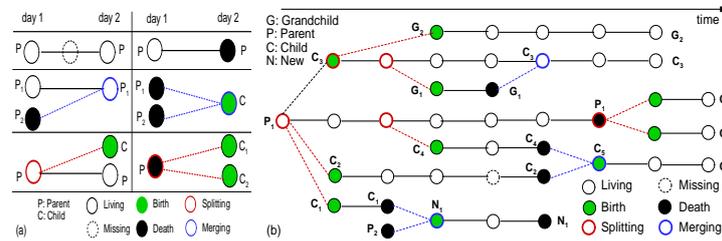

625
