**Abstract.** The spatial distribution of the dissipation rate ( $\epsilon$ ) and diapycnal diffusivity ( $\kappa$ ) in the upper ocean of the South China Sea (SCS) is presented from a measurement program conducted from 26 April to 23 May 2010. In the vertical distribution, the dissipation rates were predominantly high in the thermocline where the shear and stratification were strong. In the regional distribution, high dissipation rate and diapycnal diffusivity were observed in west of the Luzon Strait with an average dissipation rate and diapycnal diffusivity of  $8.3 \times 10^{-9} \text{ W kg}^{-1}$  and  $2.7 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$ , respectively, almost one order of magnitude higher than those in the central and southern SCS. In west of the Luzon Strait, the water column was characterized by strong shear and weak stratification. Elevated dissipation rates ( $\epsilon > 10^{-7} \text{ W kg}^{-1}$ ) and diapycnal diffusivity ( $\kappa > 10^{-4} \text{ m}^2 \text{ s}^{-1}$ ) induced by shear instability occurred in the water column. In the central and southern SCS, the water column was characterized by strong stratification and weak shear and the turbulent mixing was weak. The observed dissipation rates were found to scale positively with the shear and stratification, which was consistent with the MacKinnon-Gregg model used for the continental shelf, but different from the Gregg-Henyey scaling used for the open ocean.

## 1 Introduction

Turbulent mixing is a crucial mechanism that controls the distribution of nutrients, sediments, fresh water, and pollutants throughout the water column [Sandstrom and Elliott, 1984]. The magnitude and distribution of diapycnal diffusivity are important for large-scale ocean circulation [Saenko and Merryfield, 2005]. Assuming a balance between vertical advection and vertical diffusion for tracers, Munk [1966] reported that a global average diapycnal diffusivity of  $10^{-4} \text{ m}^2 \text{ s}^{-1}$  is required to maintain gross oceanic stratification and overturning circulation. However, measurements of ocean turbulence and released tracers [Ledwell et al., 1993] have implied the diapycnal diffusivity in the ocean interior of only  $10^{-5} \text{ m}^2 \text{ s}^{-1}$ , which is one-tenth of the value predicted by most ocean circulation models. Therefore, it has been argued that elevated mixing concentrated in rough topographies [Ledwell et al., 2000; Wu et al., 2011] would aid in explaining this discrepancy. In the past decade, elevated diapycnal diffusivities, i.e.,  $O(10^{-4} \text{ m}^2 \text{ s}^{-1})$  or higher, have been found in mixing hotspots such as seamounts [Carter et al., 2006; Lueck and Mudge, 1997], ridges [Klymak et al., 2006; Lee et al., 2006], and canyons [Carter and Gregg, 2002]. However, these elevated mixing events are highly localized. Whether such

topographically enhanced mixing is sufficiently intense or widespread to significantly increase the basin-wide average remains unclear. Using a simple averaging scheme, Kunze and Toole [1997] suggested that topographically induced mixing was insufficient to support a basin-averaged diffusivity of  $O(10^{-4} \text{ m}^2 \text{ s}^{-1})$  above a 3000 m depth in the North Pacific.

Compared with the open ocean, less attention has been given to marginal seas. In recent years, observations [Tian et al., 2009] indicated that turbulent mixing in marginal seas could make an important contribution to ocean mixing. The South China Sea (SCS), one of the largest marginal seas of the Pacific, connects to the Pacific through the Luzon Strait. Measurements and numerical simulations [Alford et al., 2015; Chang et al., 2006; Lien et al., 2005] indicated that large numbers of energetic internal tides and internal waves generated near the Luzon Strait propagate into the SCS and facilitate turbulent mixing. Considerable effort has been put forth to explore the characteristics of turbulent mixing in the SCS. Using fine-scale parameterization, Tian et al. [2009] reported a turbulent mixing distribution along a section from the northern SCS to Pacific and found that the diapycnal diffusivity in the upper 500 m of the northern SCS reached  $O(10^{-5} \text{ m}^2 \text{ s}^{-1})$ , almost two orders larger than that in the Pacific. With the Gregg-Henyey-Polzin parameterization, Yang et al. [2016] presented a three-dimensional distribution of turbulent mixing in the SCS and found diapycnal diffusivity of  $O(10^{-2} \text{ m}^2 \text{ s}^{-1})$  in the bottom water of the Luzon Strait and the Zhongsha Island Chain area. In addition to these parameterizations, some direct measurements from microstructure profilers are also available. A direct observation of turbulent dissipation was reported by Laurent [2008] who found dissipation rate as high as  $10^{-6} \text{ W kg}^{-1}$  in the shelf break of the northern SCS. Lozovatsky et al. [2013] reported regional mapping of the averaged dissipation rate in the upper pycnocline of the northern SCS and found values in the Luzon Strait as high as  $10^{-7} \text{ W kg}^{-1}$ . Yang et al. [2014] conducted direct measurements of turbulence along a section across the continental shelf and slope in the northern SCS. Their results show that the averaged dissipation rate over the shelf reached  $10^{-7} \text{ W kg}^{-1}$ , which is an order of magnitude larger than that over the slope. There is no doubt that these studies have greatly aided our knowledge of turbulent mixing in the SCS. However, the direct microstructure measurements are localized and scattered with most of them focusing on the northern SCS. Few microstructure measurements have been conducted in the central and southern SCS. In addition, there is a lack of studies assessing the parameterizations in the SCS, though they are important to the ocean models. In this work, we present a more complete direct microstructure measurement in the upper ocean of the SCS and explore the associated mixing regimes. Two fine-scale parameterizations are tested against microstructure measurements, which provide useful reference for modelers.

## 2 Measurements and Methods

The field experiment was performed prior to the South China Sea summer monsoon (SCSSM) onset from LT 26 April to 23 May 2010. A total of 82 stations were conducted in the experiment (Fig. 1). Direct turbulence measurements were collected with the Turbulence Ocean Microstructure Acquisition Profiler (TurboMAP), which is a loosely tethered, free-falling instrument ballasted to fall at  $0.5\text{-}0.7 \text{ m s}^{-1}$  and measure the microstructure of the velocity shear  $u_z$ . The TurboMAP profiler is also equipped with other sensors for measuring in situ temperature, pressure, conductivity, chlorophyll, and

turbidity variations [Wolk et al., 2002]. The sampling frequency is 512 Hz and the measurement depth range is limited to 800 m. Approximately 30 min elapsed at shallow stations or 1 h in deep water for each down- and up-cast. Continuous time series of velocity at 5-min intervals and 16-m vertical spacing between 38 and 982 m were obtained from a shipboard ADCP. The CTD casts were conducted to provide measurements of temperature and salinity. Data obtained from six moorings (Fig. 1, yellow squares) were used to perform a brief analysis of the wave field in the SCS. Moorings 1-3 were deployed over the continental shelf/slope and moorings 4-6 were deployed in the deep basin. More information regarding the moorings is given in Table 1.

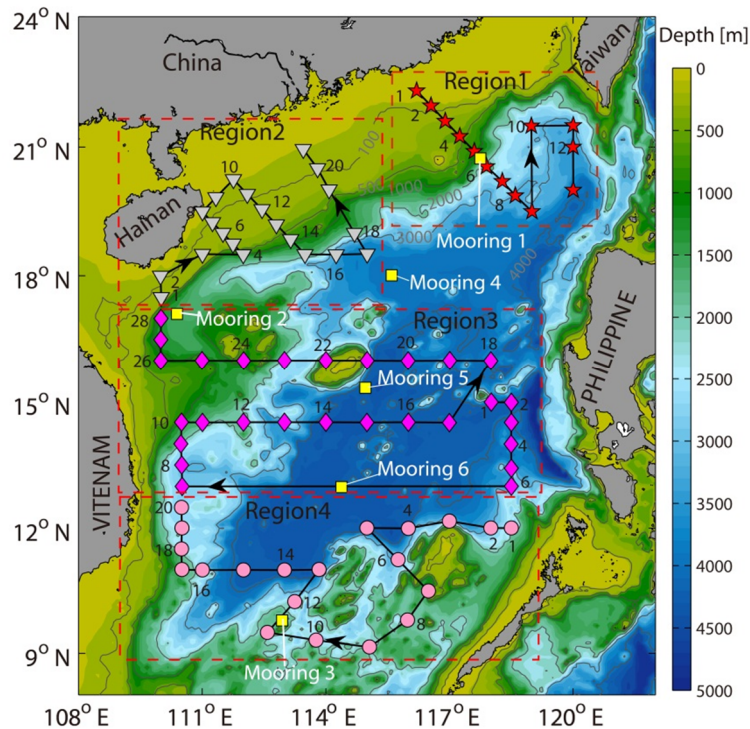

Fig. 1. Bottom topography of the SCS and observation stations (symbols). Red stars indicate the stations located in west of the Luzon Strait (region 1). Gray triangles indicate the stations located in northeast of Hainan Island (region 2). Magenta diamonds indicate the stations located in the central SCS (region 3). Pink dots indicate the stations located in the southern SCS (region 4). Station numbers (i.e., 1, 2, 4...) are indicated in each region. The arrows indicate the order of the measurement. The yellow squares indicate the locations of the moorings.

The dissipation rate is estimated with the micro-shear  $u_z$ :  $\varepsilon = 7.5\nu\langle u_z^2 \rangle = 7.5\nu \int_{k_1}^{k_2} \psi(k) dk$ , where  $\nu$  is the kinematic viscosity,  $\langle \rangle$  denotes the spatial average,  $\psi(k)$  is the shear spectra, and  $k_1$  and  $k_2$  are the integration limits.  $k_1$  is set to 1 cpm, and  $k_2$  is the highest wavenumber that is not contaminated by vibration noise. Estimates of  $\varepsilon$  are computed from the shear signal with 2-m depth segments based on a spectral analysis of the shear signal from the two probes. Dissipation data

80 are unreliable in the top 11 m due to contamination by the strong tilting of the TurboMAP profiler and ship's wake. Examples of the shear spectra and corresponding estimates of the dissipation rate are given in Fig. 2. The spectra follow the slope of Nasmyth's universal spectrum [Nasmyth, 1970]. Distinct peaks associated with high wave numbers (beyond the upper integration bound) were caused by instrument vibrations. Diapycnal diffusivity  $\kappa = \Gamma \varepsilon / N^2$  [Osborn, 1980] was calculated based on the dissipation rate  $\varepsilon$ , stratification  $N$ , and mixing efficiency  $\Gamma=0.2$  [Oakey, 1982]. The shear variance,  $S^2 = (\Delta \bar{U} / \Delta z)^2 + (\Delta \bar{V} / \Delta z)^2$ , was calculated with  $\Delta z=16$  m, where  $\bar{U}$  and  $\bar{V}$  are the zonal and meridional components of the mean horizontal velocity, respectively. The mean velocity is averaged over the time intervals of the TurboMAP measurements.

Fig. 2. Examples of (a) micro-shear and (b-g) shear spectra at different depths. The integration bounds (vertical dashed lines) and Nasmyth spectra (smooth curves) are shown.

**Table 1.** Information about the moorings.

Mooring	Latitude (°N)	Longitude (°E)	Water Depth (m)	Measurement Depth Range (m)	Measurement Duration (d/m/yr)	Time Interval (min)	Bin Size (m)

### 3 Results

#### 3.1 Water mass properties

95 Intrusion of water from the Pacific can influence the evolving water properties in the SCS. It has been confirmed by in  
situ measurements and models [Shaw, 1991; Wu and Hsin, 2012] that there is a strong intrusion of water from the Pacific  
into the SCS through the Luzon Strait. Two well-defined water masses are active in this process [Qu et al., 2000]: high-  
salinity North Pacific Tropical Water (NPTW) and low-salinity North Pacific Intermediate Water (NPIW). For simplicity,  
we divide the observations into four regions (Fig. 1): region 1 is located in west of the Luzon Strait, region 2 is located in  
100 northeast of Hainan Island, region 3 is located in the central SCS, and region 4 is located in the southern SCS. Fig. 3 shows  
the T-S curves of the SCS and western Pacific. Temperature and salinity data in the western Pacific (18.5°N-22.5°N, 124.5°  
E-128.5°E) were obtained from the World Ocean Database 2013 (<http://www.nodc.noaa.gov/OC5/woa13/woa13data.html>).  
The T-S curve in the western Pacific shows a reversed 'S' shape with NPTW and NPIW clearly identified (Fig. 3, black  
dashed curve). NPTW and NPIW correspond to the maximum salinity layer at  $\sigma_\theta \in (22.5-25.5) \text{ kg m}^{-3}$  and minimum salinity  
105 layer at  $\sigma_\theta \in (25.5-27.5) \text{ kg m}^{-3}$ , respectively. In the maximum salinity layer (22.5-25.5  $\text{ kg m}^{-3}$ ), the water column in west of  
the Luzon Strait (region 1) had a salinity maximum of 34.8 psu that approaches the maximum value of the NPTW. Salinity  
decreased gradually from the Luzon Strait to the Hainan Island (region 2) and to the central and southern SCS (region 3 and  
region 4). This trend is reversed in the minimum salinity layer (25.5-27.5  $\text{ kg m}^{-3}$ ), where the salinity slightly increased from  
the Luzon Strait to Hainan Island and to the central and southern SCS. The salinity minimum in the Pacific was found to be  
110 lower than that in the SCS. The reverse S shape becomes remarkably weak from the northern SCS to the southern SCS, a  
change to which turbulent mixing occurring in the SCS might have made a significant contribution.

Fig. 3. Relation of potential temperature vs. salinity (with the potential density  $\sigma_\theta$  in  $\text{kg/m}^3$  contours overlaid) of all stations. The black dashed curve shows the relation for potential temperature vs. salinity of the western Pacific for reference.

Fig. 4. (a) Dissipation rate ( $\epsilon$ ), (b) diapycnal diffusivity ( $\kappa$ ), (c) buoyancy frequency ( $N^2$ ), (d) shear variance ( $S^2$ ), and (e) Richardson number ( $Ri$ ) from all of the stations. The gray shading indicates the bathymetry. In (a)-(e) the boundaries of the thermocline are indicated (gray curves). The red line on the color bar of (e) represents  $Ri = 0.25$ . The vertical dashed lines divide the stations into four regions with the symbols (red stars, gray triangles, magenta diamonds, and pink dots) shown at the top of (a). These symbols correspond to the station symbols in Fig. 1.

### 3.2 Microstructure Measurements

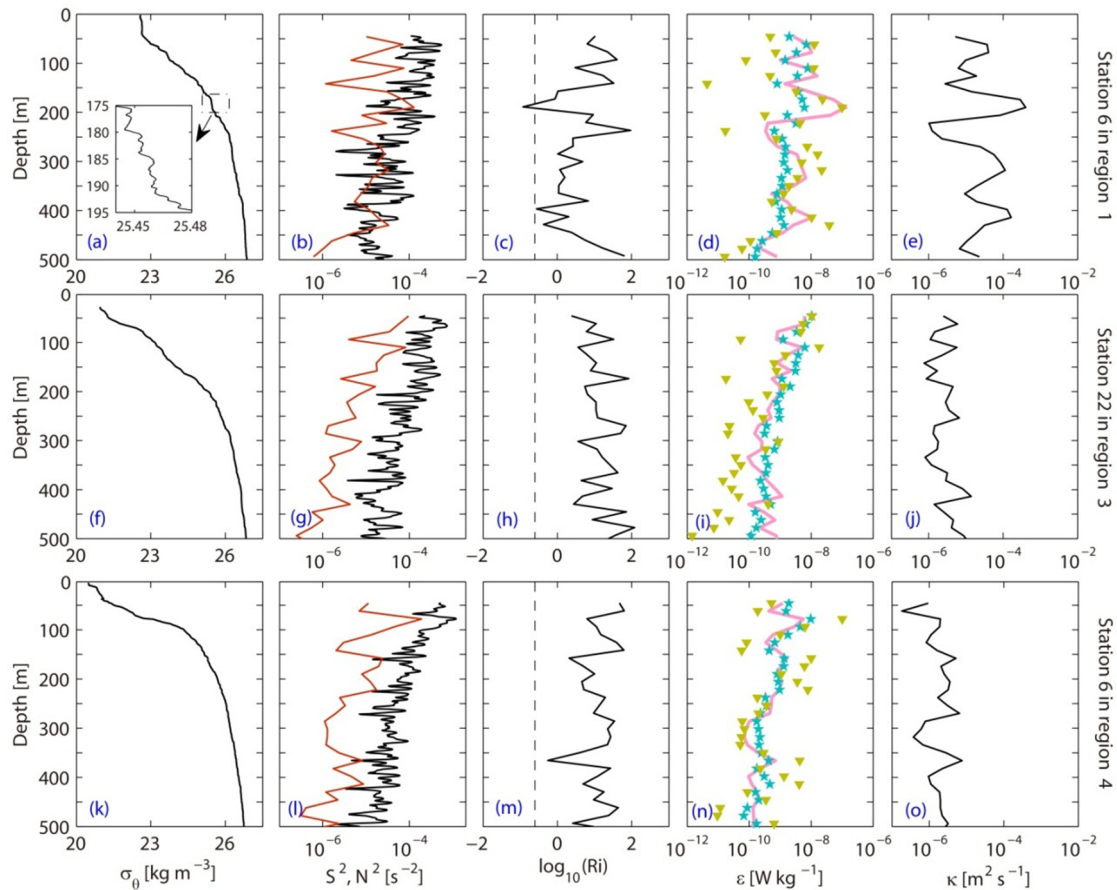

Figure 4a shows the distribution of the dissipation rate with the thermocline boundaries overlain. Different criteria have been used to define the surface mixed layer in terms of either temperature or density. Here, we defined the surface mixed layer as the depth at which the potential temperature change from the surface temperature is  $0.5\text{ }^\circ\text{C}$ . The bottom of the thermocline is defined as the depth at which the temperature gradient is equal to  $0.05\text{ }^\circ\text{C m}^{-1}$ . The surface mixed layers are slightly deep in region 1 compared with the other regions. The average depths of the surface mixed layer in regions 1-4 are 35.2, 14.7, 19.4, and 26.8 m, respectively.

In the surface mixed layer, strong turbulence was accompanied by high dissipation rates (Fig. 4a), which may be attributed to various factors, such as wind stirring, buoyancy flux, and surface waves. Below the surface mixed layer, high dissipation rates (Fig. 4a) were observed in the thermocline, with the average  $\epsilon$  in the thermocline reaching  $4.6 \times 10^{-9}\text{ W kg}^{-1}$ , which was five times larger than the value of  $8.2 \times 10^{-10}\text{ W kg}^{-1}$  below the thermocline. Strong shear (Fig. 4d) also occurred in the thermocline with an averaged  $S^2$  in the thermocline of  $3.3 \times 10^{-5}\text{ s}^{-2}$ , which was five times larger than that below the thermocline ( $6.5 \times 10^{-6}\text{ s}^{-2}$ ). The strong spatial correlation between dissipation and shear implies that shear played an important role in driving the dissipation. Contrary to the dissipation rate, the diapycnal diffusivity (Fig. 4b) in the thermocline was slightly weaker than that below the thermocline. The high diapycnal diffusivity below the thermocline was mainly due to the relatively weak stratification (Fig. 4c). The average  $N^2$  below the thermocline was  $8.4 \times 10^{-5}\text{ s}^{-2}$ , four times smaller than the value of  $3.4 \times 10^{-4}\text{ s}^{-2}$  in the thermocline.

Turbulent mixing in region 1 displayed a different feature from that of the other regions. In region 1, turbulence was more active than in other regions, with the maximum dissipation rate reaching  $10^{-6}\text{ W kg}^{-1}$  (Fig. 4a) and the maximum diapycnal diffusivity over  $10^{-3}\text{ m}^2\text{ s}^{-1}$  (Fig. 4b). In addition, region 1 had weak stratification but strong shear compared with other regions (Figs. 4c and 4d). Most of the water column in region 1 was occupied by Richardson number ( $Ri = N^2/S^2$ ) of order 1, almost two orders smaller than that in the other regions (Fig. 4e). A distinguishing feature in region 1 is that some turbulent patches with elevated dissipation rates ( $\epsilon > 10^{-7}\text{ W kg}^{-1}$ ) and diapycnal diffusivity ( $\kappa > 10^{-4}\text{ m}^2\text{ s}^{-1}$ ) were observed in the water column. These turbulent patches often occurred at depths where the Richardson number was below 0.25; for example, station 6 (between 175 and 195 m), station 8 (between 80 and 100 m), and station 11 (between 175 and 195 m) (indicated by the arrows in Fig. 4), which suggests that elevated dissipation rates and diapycnal diffusivity in the turbulent patches are likely to result from shear instability. More detail regarding the shear instability will be discussed in the following text. Compared with region 1, turbulent mixing in regions 2-4 was relatively weak, with an average  $\epsilon$  and  $\kappa$  in the

150 upper 500 m (not including the surface mixed layer) of  $1.1 \times 10^{-9} \text{ W kg}^{-1}$  and  $3.7 \times 10^{-6} \text{ m}^2 \text{ s}^{-1}$ , respectively. These two values are almost one order of magnitude smaller than those ( $\varepsilon \sim 8.3 \times 10^{-9} \text{ W kg}^{-1}$  and  $\kappa \sim 2.7 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$ ) in region 1. Weak turbulent mixing in regions 2-4 is likely to be associated with the strong stratification and weak shear.  $N^2$  (Fig. 4c) was greater than  $S^2$  (Fig. 4d) in regions 2-4 with most of the water column occupied by large Richardson number ( $Ri > 10$ ) (Fig. 4e).

155 Fig. 5. From top to bottom, three sets of profiles are from station 6 in region 1 (top panels), station 22 in region 3 (middle panels), and station 6 in region 4 (bottom panels). For each station, quantities plotted are (from left to right) potential density, shear variance (red) and buoyancy frequency (black), Richardson number (the vertical line indicates  $Ri=0.25$ ), observed (pink curves) MG model (stars) and GH model (triangles) dissipation rates, and observed diapycnal diffusivity. The observed dissipation rate and diapycnal diffusivity have been vertically averaged over the 16 m ADCP bins. The inset in (a) enlarges  
 160 the density profile to show the overturns.

To further understand the changing pattern of turbulence in the SCS, we now look in detail at the profiles of various quantities at three stations in different regions: station 6 from west of the Luzon strait (region 1), station 22 from the central

SCS (region 3), and station 6 from the southern SCS (region 4). At station 6 in region 1 (Figs. 5a-5e), the shear variance was slightly smaller than the buoyancy frequency over most of the water column (Fig. 5b). However, the shear variance exceeded the buoyancy frequency at some depths; for example, the shear variance was greater than the buoyancy frequency at a depth of 185 m, pushing the Richardson number below 0.25, which implies shear instability (Fig. 5c). Small overturns were also found in the density profile at depths of 175 to 195 m (Fig. 5a, the inset); for example, the potential density at 179.2 m was lower than that at 175.5 m. The dissipation rate (Fig. 5d) and diapycnal diffusivity (Fig. 5e) in the corresponding depths (175-195 m) were elevated by more than one order of magnitude with the diapycnal diffusivity reaching  $5.0 \times 10^{-4} \text{ m}^2 \text{ s}^{-1}$ , two orders of magnitude higher than the open-ocean background values of  $5.0 \times 10^{-6} \text{ m}^2 \text{ s}^{-1}$  [Gregg, 1989]. The dissipation rates induced by shear instability contributed significantly to the turbulent mixing in the water column. Nearly 45% of the total dissipation rate in the upper 500 m (not including the surface mixed layer) was contributed by the elevated dissipation rate from the turbulent patch. The second and third sets of profiles were from region 3 (Figs. 5f-5j) and region 4 (Figs. 5k-5o), respectively. The buoyancy frequency was higher than the shear variance (Figs. 5g and 5l), and no Richardson numbers below 0.25 were observed (Figs. 5h and 5m). The water column was occupied by dissipation rates ranging from  $10^{-10}$  to  $10^{-9} \text{ W kg}^{-1}$  (Figs. 5i and 5n) and diapycnal diffusivity of  $O(10^{-6} \text{ m}^2 \text{ s}^{-1})$  (Figs. 5j and 5o), that is, the same level as the background of the open ocean.

Because the dissipation rates were dominantly large in the thermocline, we calculate the averaged dissipation rate  $\langle \varepsilon \rangle_T$  as well as the averaged diapycnal diffusivity  $\langle \kappa \rangle_T$  in the thermocline to compare the magnitudes of the dissipation rate and diapycnal diffusivity in different regions.  $\langle \varepsilon \rangle_T$  and  $\langle \kappa \rangle_T$  are given by

$$\langle \varepsilon \rangle_T = 1/(z_b - z_t) \int_{z_b}^{z_t} \varepsilon dz \text{ and } \langle \kappa \rangle_T = 1/(z_b - z_t) \int_{z_b}^{z_t} \kappa dz,$$

where  $z_b$  and  $z_t$  are the bottom and top locations of the thermocline, respectively. The dissipation rate and diapycnal diffusivity affected by the surface mixed layer were excluded before calculating  $\langle \varepsilon \rangle_T$  and  $\langle \kappa \rangle_T$ . Fig. 6a shows the averaged dissipation rate in the thermocline.  $\langle \varepsilon \rangle_T$  displayed a decreasing trend toward the south from  $O(10^{-8} \text{ W kg}^{-1})$  in west of the Luzon Strait (region 1) to  $O(10^{-9} \text{ W kg}^{-1})$  in the southern SCS (region 4). In region 1,  $\langle \varepsilon \rangle_T$  ranged from  $1.8 \times 10^{-9}$  to  $5.0 \times 10^{-8} \text{ W kg}^{-1}$  with a mean value of  $1.8 \times 10^{-8} \text{ W kg}^{-1}$ , which was 7 times, 9 times, and 12 times higher than the mean values of region 2 ( $2.5 \times 10^{-9} \text{ W kg}^{-1}$ ), region 3 ( $2.1 \times 10^{-9} \text{ W kg}^{-1}$ ), and region 4 ( $1.5 \times 10^{-9} \text{ W kg}^{-1}$ ), respectively. Elevated  $\langle \kappa \rangle_T$  was also observed in region 1 (Fig. 6b). The average  $\langle \kappa \rangle_T$  in region 1 was  $3.5 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$ , which was an order of magnitude greater than the values of region 2 ( $3.3 \times 10^{-6} \text{ m}^2 \text{ s}^{-1}$ ), region 3 ( $2.2 \times 10^{-6} \text{ m}^2 \text{ s}^{-1}$ ), and region 4 ( $2.1 \times 10^{-6} \text{ m}^2 \text{ s}^{-1}$ ). One prominent feature in the northern SCS is that the mean of  $\langle \kappa \rangle_T$  in region 1 was 11 times higher than the value in region 2 while the mean of  $\langle \varepsilon \rangle_T$  in region 1 was only 7 times higher than that the value in region 2. This difference mainly resulted from the weak stratification in region 1 (Fig. 4c).

Microstructure measurements at different stations were taken at different times; thus, spring-neap tides may be one of the factors that affect the variability of  $\langle \varepsilon \rangle_T$  and  $\langle \kappa \rangle_T$ . To explore the effect of spring-neap tides on the variability of  $\langle \varepsilon \rangle_T$  and  $\langle \kappa \rangle_T$ , we obtained the barotropic tides from the global inverse tide model (TPXO) [Egbert and Erofeeva, 2002], which

give us the time information of spring-neap tides during the period of observation. Only the barotropic tides at 18°N, 114°E were extracted because the spring-neap tides in different locations of the SCS occur almost simultaneously. The 14-day spring-neap cycles were well-represented in the extracted barotropic tides (Fig. 6c). A comparison of  $\langle \varepsilon \rangle_T$  and  $\langle \kappa \rangle_T$  to the extracted tides suggests that the main variability of  $\langle \varepsilon \rangle_T$  and  $\langle \kappa \rangle_T$  and their distribution characteristics were not attributed to the effect of spring-neap tides; for example, though stations in regions 1 and 3 spanned neap and spring tides (see Fig. 6c, stars and diamonds), the averaged  $\langle \varepsilon \rangle_T$  and  $\langle \kappa \rangle_T$  in region 1 were still an order of magnitude greater than the values in region 3 (Figs. 6a and 6b); furthermore, stations 1-6 in region 3 were conducted during the spring tide (Fig. 6c, 2 May to 3 May, diamonds), but their  $\langle \varepsilon \rangle_T$  and  $\langle \kappa \rangle_T$  values were slightly lower than those of stations 7-17, which were measured during the neap tide (Fig. 6c, 9 May to 12 May, diamonds).

205 Fig. 6. (a) The average dissipation rate  $\langle \varepsilon \rangle_T$  and (b) the average diapycnal diffusivity  $\langle \kappa \rangle_T$  in the thermocline. The vertical lines indicate the 95% bootstrapped confidence interval. The vertical dashed lines divide the stations into four regions with symbols (red stars, gray triangles, magenta diamonds, and pink dots) shown at the top of (a). These symbols correspond to the station symbols in Fig. 1. (c) Time series of the barotropic tidal velocity ( $u_{bt}$ ) predicted from TPXO 7.1 with the station  
 210 symbols overlain.

Here we provide a brief summary for this section. Our observation indicates that strong turbulent mixing was concentrated in west of the Luzon Strait (region 1), with stratification and shear variance made significant contributions. The water column in region 1 had weaker stratification but stronger shear than those in other regions. In this condition, shear instability events occasionally occurred in region 1 and produced elevated dissipation and diapycnal diffusivity. In regions 2-4, instead, the water column was characterized by weak shear and strong stratification. Shear was no longer sufficiently high to produce subcritical Richardson numbers. The resulting turbulence was weak. Our analysis indicates that the spatial distribution of turbulent mixing with large  $\langle \varepsilon \rangle_T$  and  $\langle \kappa \rangle_T$  concentrated in west of Luzon Strait does not result from the effect of spring-neap tides.

### 3.3 Parameterizations of turbulence

In this section we evaluate two models for parameterizing the dissipation rate in terms of more easily observed or modeled quantities, such as stratification and shear. One wave-wave interaction parameterization [Gregg, 1989; MacKinnon and Gregg, 2003] in the open ocean is the Gregg-Henyey scaling (known as the GH model) given by

$$\varepsilon_{GH} = 1.8 \times 10^{-6} f \cosh^{-1} \left( \frac{N_0}{f} \right) \left( \frac{S^4}{S_{GM}^4} \right) \left( \frac{N^2}{N_0^2} \right) \text{ and}$$

$$S_{GM}^4 = 1.66 \times 10^{-10} \left( \frac{N^2}{N_0^2} \right)^2,$$

where  $f$  is the Coriolis frequency,  $S$  is the low-frequency/low-mode resolved shear, and  $N_0$  is a reference buoyancy frequency. Another analytical model [MacKinnon and Gregg, 2003] is the MacKinnon-Gregg model (known as the MG model) given by

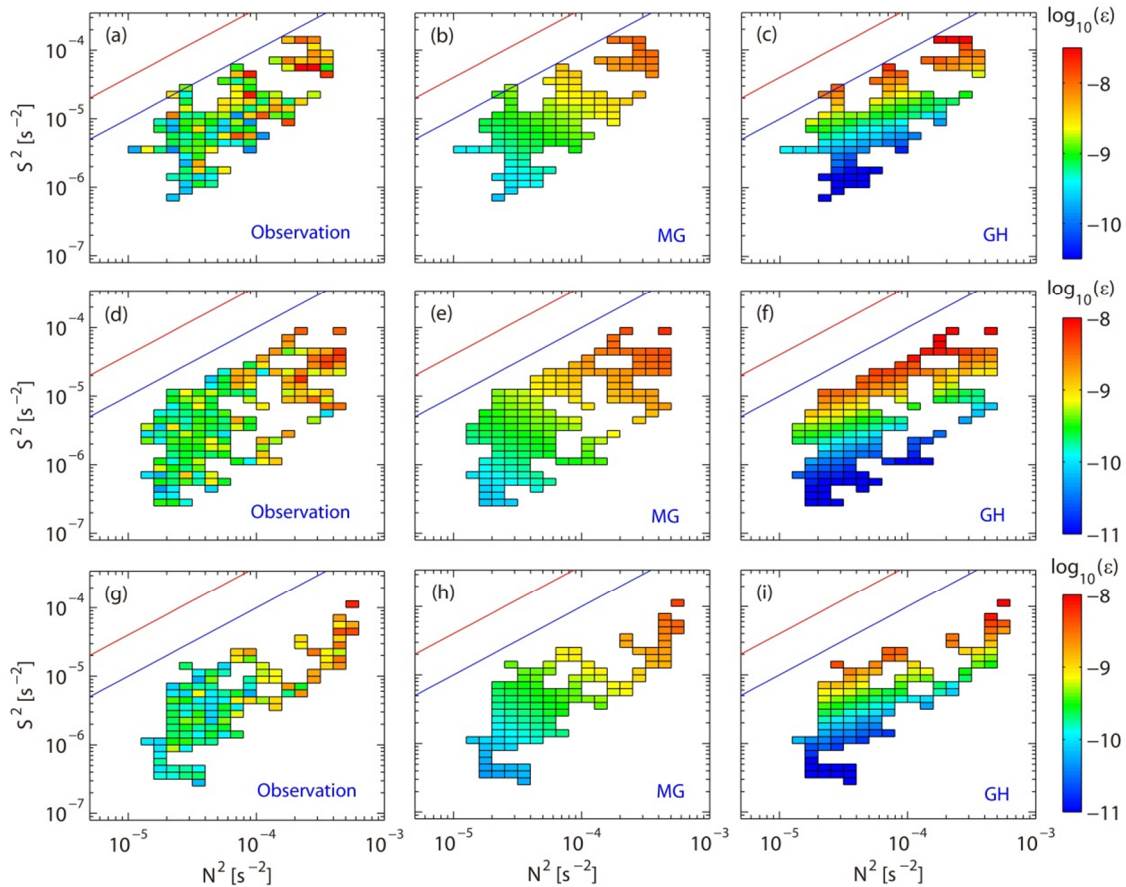

$$\varepsilon_{MG} = \varepsilon_0 \left( \frac{N}{N_0} \right) \left( \frac{S}{S_0} \right),$$

where  $S_0 = N_0 = 3$  cph and  $\varepsilon_0$  is an adjustable constant that gives the model dissipation rate the same cruise average as the observational data. The adjustable constant  $\varepsilon_0$  shows great variability in different regions and seasons, spanning from  $10^{-10}$   $\text{W kg}^{-1}$  to more than  $10^{-8}$   $\text{W kg}^{-1}$  [MacKinnon and Gregg, 2005; Palmer et al., 2008; van der Lee and Umlauf, 2011; Xie et al., 2013]. This regional and temporal variability of  $\varepsilon_0$  strongly suggests the importance of different physical processes on setup and maintenance of the background levels of turbulent dissipation. Here, we assess the two models for parameterization of the turbulence in the northern SCS (dissipation data are from the stations in region 1 and region 2), central SCS (dissipation data are from the stations in region 3), and southern SCS (dissipation data are from the stations in region 4). Different values of parameter  $\varepsilon_0$  are selected for the parameterizations due to their different mixing backgrounds:  $\varepsilon_0 = 1.65 \times 10^{-9}$   $\text{W kg}^{-1}$  for the northern SCS,  $\varepsilon_0 = 0.96 \times 10^{-9}$   $\text{W kg}^{-1}$  for the central SCS, and  $\varepsilon_0 = 0.50 \times 10^{-9}$   $\text{W kg}^{-1}$  for the southern SCS. All of the data affected by the surface mixed layers or bottom mixed layers were excluded for the parameterizations. To reduce the bias introduced by the different vertical resolutions of the shear and stratification data, density was first interpolated onto the

ADCP grid and  $N^2$  was computed from finite differencing. Accordingly, the dissipation rates were vertically averaged over the 16-m ADCP bins.

The results of the parameterizations are shown in Fig. 7. The observed dissipation rates in the SCS (Fig. 7, left column) increased with increasing buoyancy frequency and shear. The GH model fails to reproduce these kinematic relationships (Fig. 7, right column). The dependence of  $\varepsilon_{GH}$  on shear is too strong, with the dissipation rates underestimated in weak shear.  $\varepsilon_{GH}$  also varies inversely with the buoyancy frequency for a given level of shear, contrary to the observation (Fig. 7, left column). Instead, the MG model dissipation rates (Fig. 7, middle column) display a qualitatively consistent pattern with the observed data (Fig. 7, left column). Both the observed and MG model dissipation rates scale positively with shear and the buoyancy frequency. In the northern SCS, the turbulence was more complicated than the predictions of the MG model. The MG model (Fig. 7b) underestimated the elevated dissipation rates that scattered in Fig. 7a; for example, the MG model underestimated the elevated dissipation rates at ( $N^2=6.5\times 10^{-5} \text{ s}^{-2}$ ,  $S^2=5.0\times 10^{-6} \text{ s}^{-2}$ ), ( $N^2=1.0\times 10^{-4} \text{ s}^{-2}$ ,  $S^2=1.0\times 10^{-5} \text{ s}^{-2}$ ), and ( $N^2=7.9\times 10^{-5} \text{ s}^{-2}$ ,  $S^2=2.0\times 10^{-5} \text{ s}^{-2}$ ).

250 Fig. 7. Dissipation rates of observation  $\varepsilon_{OB}$  (left column), MG model  $\varepsilon_{MG}$  (middle column), and GH model  $\varepsilon_{GH}$  (right column) averaged in bins of 16 m buoyancy frequency ( $N^2$ ) and 16 m shear variance ( $S^2$ ). All data affected by the surface

mixed layers or bottom mixed layers were excluded. (a-c) show the results of the stations in the northern SCS, (d-f) show the results of the stations in the central SCS, and (g-i) show the results of the stations in the southern SCS. The boundaries of  $Ri=0.25$  (oblique red lines) and  $Ri=1$  (oblique blue lines) are shown for reference.

255 To further evaluate the success of the two models in parameterizing the observed dissipation rates, we explore the separate shear and buoyancy frequency dependence (Fig. 8). They are equivalent to integrating the two-dimensional plots in Fig. 7 horizontally and vertically. Both models reproduce the slope of the dissipation rate versus the buoyancy frequency ( $\epsilon \propto N^2$ ) (Figs. 8a, 8c, and 8e), though the GH model dissipation rates are too large on average. However, the two models show large differences in the trend of the dissipation rate versus shear (Figs. 8b, 8d, and 8f). The MG model successfully captures the essential kinematic relationship between the dissipation rate and shear, whereas the GH model dissipation rates have a much steeper relationship with shear.

260

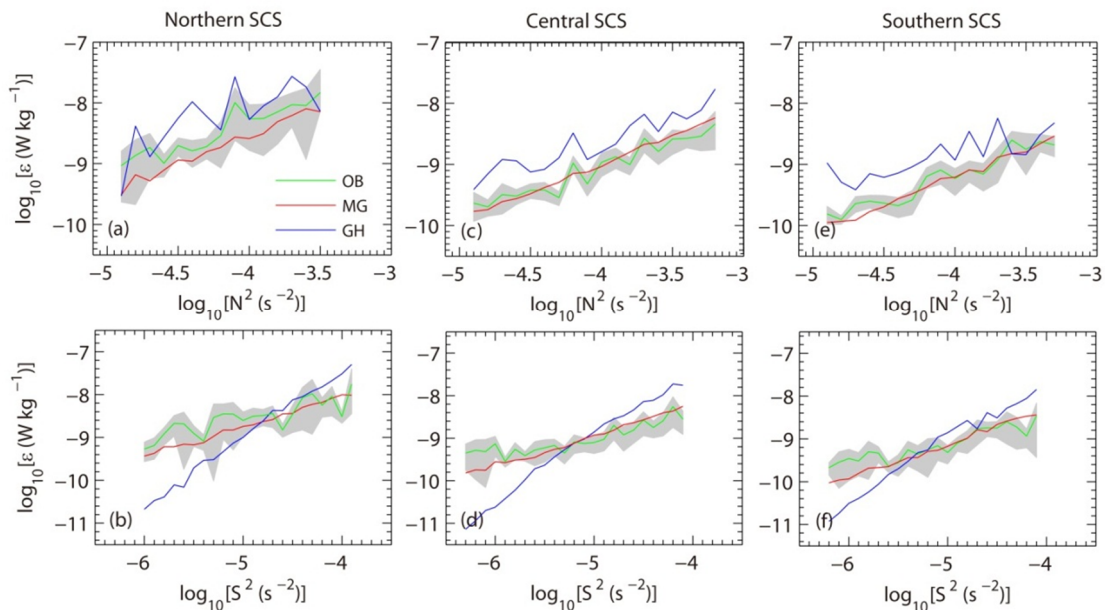

Fig. 8. Average dissipation rate calculated in bins of buoyancy frequency ( $N^2$ ) and shear variance ( $S^2$ ) for the northern SCS (a-b), central SCS (c-d), and southern SCS (e-f). The green, red, and blue curves are the results of the observation, MG model, and GH model, respectively. The grey shading indicates the 95% bootstrapped confidence interval for the observed dissipation rates.

265

Comparing the three regions, we find that the confidence intervals of the observed dissipation rates in the northern SCS (Figs. 8a and 8b) were wider than those in the central and southern SCS (Figs. 8c-8f). In addition, the observed dissipation rates in the northern SCS were slightly larger and showed greater fluctuations than the MG model dissipation rates (Fig. 8a and 8b). The wide confidence intervals and high observed dissipation rates in Figs. 8a and 8b mainly resulted from the elevated dissipation rates scattered in Fig. 7a. The MG model underestimated these elevated dissipation rates (comparing Fig.

270

7a with Fig. 7b). To explore this underestimation, we directly compared the model dissipation rates with the observed  
dissipation rates at three selected stations (Fig. 5, fourth column). For the stations from regions 3 and 4 (Figs. 5i and 5n), the  
relationships between the observed dissipation rates (pink curves) and the GH model dissipation rates (triangles) were poor,  
with the GH model dissipation rates deviating from the observed data by one order of magnitude. Instead, the MG model  
dissipation rates (stars) fared better than the GH model dissipation rates against the observed data. For station 6 from region  
1 (Fig. 5d), the MG model dissipation rates also agreed quite well with the observed data, except for the elevated dissipation  
rates induced by shear instability; for example, the MG model underestimated the elevated dissipation rates at depths of 175  
to 195 m by more than one order of magnitude. The elevated dissipation rates scattered in Fig. 7a mainly resulted from the  
dissipation rates induced by shear instability. However, the GH model dissipation rates seemed to agree with the elevated  
dissipation rates induced by shear instability (between 175 and 195 m). This agreement may be because the dissipation rates  
resulting from shear instability depends on the Richardson number and because the GH model also demonstrates Richardson  
number dependency.

#### 4 Summary and discussion

We analyzed observations of turbulent dissipation and mixing in the SCS with microstructure data obtained from April  
26 to May 23 2010. The observations are divided into four regions: region 1 in west of the Luzon Strait, region 2 in northeast  
of Hainan Island, region 3 in the central SCS, and region 4 in the southern SCS. In the vertical distribution, large  $\epsilon$  values  
below the surface mixed layer were concentrated in the thermocline where the shear and stratification were strong. In the  
regional distribution, turbulent mixing was more active in west of the Luzon Strait with the mean  $\langle \epsilon \rangle_T$  reaching  $1.8 \times 10^{-8} \text{ W}$   
 $\text{kg}^{-1}$ , which is 9 times and 12 times larger than the values in the central ( $2.1 \times 10^{-9} \text{ W kg}^{-1}$ ) and southern ( $1.5 \times 10^{-9} \text{ W kg}^{-1}$ ) SCS,  
respectively. Elevated  $\langle \kappa \rangle_T$  were also found in west of the Luzon Strait, i.e.,  $O(10^{-5} \text{ m}^2 \text{ s}^{-1})$ , which is an order of magnitude  
higher than the value of  $5 \times 10^{-6} \text{ m}^2 \text{ s}^{-1}$  in the open-ocean thermocline [Gregg, 1989]. This spatial pattern is consistent with the  
mixing distribution reported by Yang et al. [2016] who estimated the dissipation rate and diapycnal diffusivity with the  
Gregg-Henyey-Polzin parameterization and found strong turbulent mixing in west of the Luzon Strait. Our estimates of  
diapycnal diffusivity in west of the Luzon Strait are similar to those of Tian et al. [2009] who estimated diapycnal diffusivity  
of  $O(10^{-5} \text{ m}^2 \text{ s}^{-1})$  in the upper 500 m with fine-scale parameterization. In contrast, Yang et al. [2016] estimated the average  
diapycnal diffusivity in the upper 500 m as large as  $O(10^{-3} \text{ m}^2 \text{ s}^{-1})$  in west of the Luzon Strait; the larger values may be  
attributed to various factors such as measuring methods and observation seasons.

The turbulent mixing in different regions displays different mixing features, to which shear variance and stratification  
have made significant contribution. In west of the Luzon Strait (region 1), the shear was stronger and the stratification was  
weaker than those in other regions. Shear instability events occasionally occurred in this condition and produced elevated  
dissipation and diapycnal diffusivity. Although the turbulent patches induced by shear instability were occasional and sparse,  
they significantly contributed to the turbulent mixing in the water column. In the central and southern SCS (region 3 and

region 4), the water column was characterized by weak shear and strong stratification. Shear was no longer sufficient to  
305 produce subcritical Richardson numbers and the turbulence was weak. The strong spatial correlation between high  
dissipation rates and strong shear presented in the thermocline in west of the Luzon Strait suggests that shear was one of the  
important drivers of the turbulent mixing. The strong shear may result from the internal tides or internal waves generated  
near the Luzon Strait. Unfortunately, our observational data record was not long enough to identify these waves and analyze  
their contribution to the mixing.

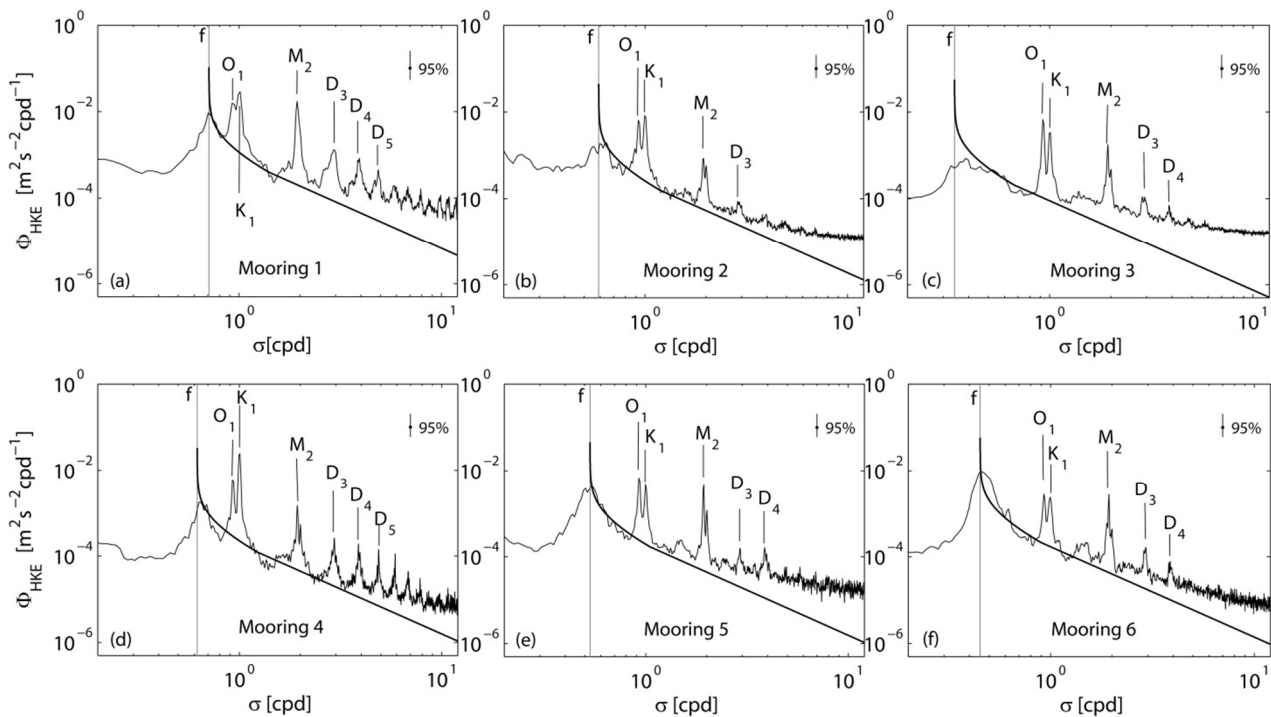

310 To predict realistic climate and circulation, mixing must be accurately represented in ocean models. Mapping of the  
dissipation rates throughout the ocean is a daunting task. However, this task can be made considerably easier if mixing can  
be estimated from more easily observed or modeled quantities, such as shear, stratification, and latitude. Two models (the  
GH model and MG model) were evaluated for parameterizing the dissipation rate in the SCS. These two models were  
derived from the eikonal model of Henyey et al., [1986] and are applicable to parameterize the dissipation controlled by  
315 wave-wave interactions that transfer energy from large-scale waves to small-scale waves [MacKinnon and Gregg, 2005].  
The GH model is based on the assumption that the waves are statistically stationary, with the energy of small-scale waves  
and the shear of the large-scale waves maintain a particular relationship through the Garrett-Munk (GM) spectrum [Garrett  
and Munk, 1975]. GH model is typically evaluated for the internal wave field with the GM spectral shape [Gregg, 1989].  
The MG model is proposed by MacKinnon and Gregg [2003] to parameterize the turbulence over the continental shelf. It is  
320 found to be suitable for the wave field in which the energy and shear are dominated by the near-inertial motions, internal  
tides, or low frequency internal waves [MacKinnon and Gregg, 2003; Palmer et al., 2008; Xie et al., 2013].

Statistical analysis shows the dissipation in the SCS to be proportional to both the shear and buoyancy frequencies, in  
marked contrast to the predictions of the GH model, but consistent with the predictions of the MG model. The disagreement  
of the GH model may be associated with the wave field in the SCS. Previous studies [Polzin et al., 1995; Wijesekera et al.,  
325 1993] have indicated that the predictions of the GH model would exhibit departure from the observed dissipation by more  
than one order of magnitude in regions where the wave field deviates from the GM spectrum. Thus, it is appropriate to  
examine the wave field in the SCS. Data obtained from six moorings deployed in the SCS (Fig. 1, yellow squares) were used  
to estimate the horizontal kinetic energy spectra. Though the data were obtained from different periods, they reflected the  
main characteristics of the wave field in the SCS. The spectra (Fig. 9) show significant peaks in the local inertial ( $f$ ), diurnal  
330 ( $O_1$  and  $K_1$ ), and semidiurnal ( $M_2$ ) frequencies, which imply that energy was primarily dominated by the near-inertial  
motions and internal tides. Within the internal wave band, significant peaks were also observed at higher tidal harmonic  
frequencies such as  $D_3$ ,  $D_4$ , and  $D_5$ . These energetic internal tides and harmonic internal waves cannot be well described by  
the GM spectrum. Furthermore, the spectra deviated from the GM spectrum at high frequencies ( $\sigma > 3$  cpd), which is  
especially evident in the spectra of the moorings from west of the Luzon Strait (mooring 1) and the southern SCS (mooring  
335 3). These observations are not supportive of the assumption that the GH model is based on. The GH model is typically  
evaluated for the wave field with the GM spectral shape. In contrast, some of our observations support the MG model, that is  
the wave field is dominated by near-inertial waves and internal tides and the dissipation rates scale positively with shear and

stratification. Overall, the MG model succeeds in parameterizing the turbulence in the SCS, except for some elevated  
 dissipation rates induced by shear instability. The MG model tends to underestimate these elevated dissipation rates. This is  
 340 not surprising because the MG model, which is based on wave-wave interactions, represents bulk averages of turbulent  
 properties and does not reproduce individual shear instability events [MacKinnon and Gregg, 2005].

The replication of the turbulence behavior greatly depends on the correct choice of model and appropriate tuning of the  
 free parameters. The resolution of the shear and stratification is another factor in determining the success of models in  
 parameterizing the turbulence [Palmer et al., 2013]. Although the MG model can reproduce the dissipation in the SCS for  
 345 our chosen vertical resolution (16 m), whether the distribution of the observed would change with finer resolution of shear  
 and stratification is still an open problem. However, at least on the scale of internal waves (16 m), the MG model is clearly a  
 better model than the GH model for the parameterization of turbulence in the upper ocean of the SCS, which provides a  
 useful reference for modelers. Additional data with higher resolution are required to robustly fix this model in the near future.

350 Fig. 9. (a-f) Rotary spectra (clockwise plus counterclockwise) of horizontal kinetic energy for the six moorings deployed in  
 the SCS. Spectra are averaged over  $z \in [60:270]$  m. The canonical Garrett and Munk spectrum is shown for reference  
 (smooth curve). The vertical lines represent various frequencies ( $f$ ,  $O_1$ ,  $K_1$  ...). The 95% statistical significance level is  
 indicated by the vertical bar in the upper-right corner.

### Author contribution

355 Xiao-Dong Shang and Gui-Ying Chen designed and carried out the experiments. Chang-Rong Liang prepared the manuscript with contributions from all co-authors.

### Competing interests

The authors declare that they have no conflict of interest.

### Acknowledgments
