11 **Abstract.** Ecosystem models are used to understand ecosystem dynamics and ocean biogeochemical cycles and require  
12 optimum physiological parameters to best represent biological behaviours. These physiological parameters are often tuned up  
13 empirically, while ecosystem models have evolved to increase the number of physiological parameters. We developed a three-  
14 dimensional (3D) lower trophic level marine ecosystem model known as the Nitrogen, Silicon and Iron regulated Marine  
15 Ecosystem Model (NSI-MEM) and employed biological data assimilation using a micro-genetic algorithm to estimate 23  
16 physiological parameters for two phytoplankton functional types in the western North Pacific. **The estimation of the parameters**  
17 **was based on a one-dimensional simulation that referenced satellite data for constraining the physiological parameters.** The 3-  
18 D NSI-MEM optimised by **the data** assimilation improved the timing of a modelled plankton bloom in the subarctic and  
19 subtropical regions compared to **the model** without data assimilation. Furthermore, the model was able to **improve** not only  
20 surface concentrations of phytoplankton but also **their** subsurface maximum concentrations. Our results showed that surface  
21 data assimilation of **physiological** parameters from two **contrasting** observatory stations benefits the representation of vertical  
22 plankton distribution in the western North Pacific.

25 The Western North Pacific (WNP) region is a high-nutrient, low-chlorophyll (HNLC) region where biological productivity  
26 is lower than expected for the prevailing surface macronutrient conditions. There are both Western Subarctic Gyre and  
27 Subtropical Gyre comprising the Oyashio and the Kuroshio, respectively (Fig. 1 (a)). Between the gyres (i.e. the Kuroshio–  
28 Oyashio transition region), horizontal gradients of temperature and phytoplankton concentration in the surface water are  
29 generally large due to meanders in the Kuroshio extension jet and mesoscale eddy activity (Qiu and Chen, 2010; Itoh et al.,  
30 2015). The relatively low productivity in the HNLC region is due to low dissolved iron concentrations (e.g. Tsuda et al., 2003),  
31 because iron is one of the essential micronutrients for many phytoplankton species. The source of iron for the WNP region is  
32 not only from air-born dust but also from iron transported in the intermediate water from the Sea of Okhotsk to the Oyashio  
33 region (Nishioka et al., 2011). Since the WNP region exhibits many complex physical and biogeochemical characteristics as  
34 referred to above, it is difficult even for state-of-the-art eddy-resolving models to reproduce them.

35 Processes of growth, decay and interaction by plankton are critical to understand the oceanic biogeochemical cycles and the  
36 lower trophic level (LTL) marine ecosystems. There are many LTL marine ecosystem models ranging from simple nutrient,  
37 phytoplankton and zooplankton models to more complicated models including carbon-, oxygen-, silicate-, iron-cycles and so  
38 forth (e.g. Fasham et al., 1990; Edwards and Brindley, 1996; Lancelot et al., 2000; Yamanaka et al., 2004; Blauw et al., 2009).  
39 Coupling LTL marine ecosystem models to ocean general circulation models (OGCMs) and earth system models enables  
40 three-dimensional (3D) quantitative descriptions of the ecosystem and its temporally fine variability (e.g. Aumont and Bopp,  
41 2006; Follows et al., 2007; Buitenhuis et al., 2010; Sumata et al., 2010; Hoshiba and Yamanaka, 2016).

42 Physiological parameters are usually fixed in the models on the basis of local estimations and applied homogeneously to a  
43 basin-scaled ocean, although the values of physiological parameters should depend on the environments of regions. Moreover,  
44 physiological parameters have been often tuned up empirically and arbitrarily. The fact that the number of parameters increases  
45 with prognostic and diagnostic variables makes it more difficult to tune them. In order to reproduce observed data such as  
46 spatial distribution of phytoplankton biomass and timing of a plankton bloom, it is required to reasonably estimate the  
47 physiological parameters.

48 In previous studies using LTL marine ecosystem models, various approaches for data assimilation were introduced as  
49 methods of estimating optimal physiological parameters (e.g. Kuroda and Kishi, 2004; Fiechter et al., 2013; Toyoda et al.,  
50 2013; Xiao and Friedrichs, 2014). On the other hand, Shigemitsu et al. (2012) applied a unique assimilative approach to a LTL  
51 marine ecosystem model, using a mirco-genetic algorithm ( $\mu$ -GA) (Krishnakumar, 1990). For the western subarctic Pacific,  
52 they showed that the  $\mu$ -GA worked well in the one-dimensional (1D) nitrogen-, silicon- and iron regulated marine ecosystem  
53 model (NSI-MEM: Fig. 2), that was based on NEMURO (North pacific Ecosystem Model for Understanding Regional  
54 Oceanography: Kishi et al., 2007) but differed in the following points: (1) the introduction of an iron cycle, including dissolved  
55 and particulate iron, whereby the dissolved iron explicitly regulates phytoplankton-photosynthesis; (2) adoption of  
56 physiologically more consistent optimal nutrient-uptake (OU) kinetics compared to the classical Michaelis–Menten equation

57 and (3) the division of detritus into two types of small and large sizes that exhibit different sinking rates.

58 Our objective is to improve simulation of the LTL ecosystem in the WNP region by further introducing: (1) a physical field  
59 from an eddy-resolving OGCM with a horizontal resolution of  $0.1^\circ$  and (2) an assimilated physiological parameter estimation  
60 for two different phytoplankton groups. The details of the model and  $\mu$ -GA settings are described in Section 2. We compare  
61 the simulation results with/without the parameter optimisation to observed data, and confirm the effects of changing parameters  
62 in Section 3. We mainly focused on the seasonal variations of phytoplankton in the pelagic region. Finally, the results are  
63 summarized in Section 4.

## 64 2 Model and data description

### 65 2.1 3D NSI-MEM

66 We used the marine ecosystem model, NSI-MEM that includes two phytoplankton functional types (PFTs), namely non-  
67 diatom small phytoplankton (PS) and large phytoplankton representing diatoms (PL) (Fig. 2). In order to run the NSI-MEM  
68 in three-dimensional space, we used a physical field obtained from the Meteorological Research Institute Multivariate Ocean  
69 Variational Estimation for the WNP region (MOVE-WNP) (Usui et al., 2006). The MOVE-WNP system is composed of the  
70 OGCM (the Meteorological Research Institute community ocean model) and a multivariate 3D variational analysis scheme  
71 that synthesizes the observed information such as temperature, salinity and sea surface height.

72 The model domain extends from  $15^\circ$  N to  $65^\circ$  N and  $117^\circ$  E to  $160^\circ$  W in the WNP region, with a grid spacing of  $1/10^\circ \times$   
73  $1/10^\circ$  around Japan and  $1/6^\circ$  to the north of  $50^\circ$  N and to the east of  $160^\circ$  E (Fig. 1 (a)). There are 54 vertical levels with layer  
74 thicknesses increasing from 1 m at the surface to 600 m at the bottom. The model is forced by factors including surface wind,  
75 heat flux and freshwater flux. The details of the surface forcing are presented by Tsujino et al. (2011). Short wave radiation  
76 input and dust flux were the same as those of a global climate model (Model for Interdisciplinary Research on Climate,  
77 MIROC; Watanabe et al., 2011). A part of the dust flux (3.5 %; Shigemitsu et al., 2012) was regarded as the iron dust, and  
78 1 % of the iron dust was assumed to dissolve into the sea surface (Parekh et al., 2004). The other iron dust was transported to  
79 the lower layers and dissolved, which was the same process as Shigemitsu et al. (2012). River run-off as a freshwater supply  
80 was from CORE ver. 2 forcing (Large and Yeager, 2009), in which the river source had the nitrate concentration value of 29  
81  $\mu\text{mol/l}$  (Conha et al., 2007) and the silicate concentration value of 102  $\mu\text{mol/l}$  adjusted in the range between  $\text{Si/N} = 0.2$  to 4.3  
82 (Jickells, 1998). Nitrate and silicate sources were only rivers, and iron supply was only from the dust in the model setting. In  
83 order to buffer artificial high concentrations near the side edge of the model domain, nutrients near the southern and eastern  
84 boundary of the model domain were only restored for 43 minutes to 3.6 hours to the values provided by the Meteorological  
85 Research Institute Community Ocean Model (MEM-MRI.COM) participating in MARine Ecosystem Model Intercomparison  
86 Project ([https://pft.ees.hokudai.ac.jp/maremip/data/MAREMIPh\\_var\\_list.html](https://pft.ees.hokudai.ac.jp/maremip/data/MAREMIPh_var_list.html)). The physical field used in our ecosystem  
87 model had already been confirmed to reproduce realistic salinity, velocity and temperature fields in a previous study (Usui et  
88 al., 2006). Using a physical one-day averaged field, we ran the NSI-MEM to simulate the years between 1985 and 1998.

89 We divided the model domain into two provinces (green and yellow regions in Fig. 1 (b)) using the following province map  
 90 instead of maps divided by latitude–longitude lines as in previous studies (e.g. Longhurst, 1995; Toyoda *et al.*, 2013). The  
 91 province map is based on the dominant phytoplankton species and nutrient limitations (Hashioka *et al.*, in preparation) and  
 92 sets different ecosystem parameters (see details in Section 2.3) for each province (hereafter, ‘Parameter-optimised case’; Table  
 93 1). For each province, the respective parameters estimated by the  $\mu$ -GA and the 1D NSI-MEM were employed to those in  
 94 the 3D NSI-MEM. A large gap in a horizontal-distribution of phytoplankton can appear on the boundary of  
 95 the two provinces in Fig. 1 (b), due to a gap in the different parameter sets at the boundary. In order to smooth  
 96 the gap in parameter values at the boundary between the two provinces in Fig. 1 (b), the parameters were varied as a function  
 97 of the sea surface temperature (SST) annually averaged for 1998 (Fig. 1 (c)) for our ‘SST-dependent case’ (Table 1). The  
 98 parameters were interpolated/extrapolated according to the following equation:

$$99 \quad P(x) = P_{St.S1} + (P_{St.KNOT} - P_{St.S1}) \times \frac{SST(x) - SST_{St.S1}}{SST_{St.KNOT} - SST_{St.S1}}, \quad (1)$$

100 where  $P(x)$ ,  $P_{St.S1}$  and  $P_{St.KNOT}$  are ecosystem parameters for a point ( $x$ ), St. S1 and St. KNOT, respectively. St. KNOT and  
 101 St. S1 are typical observational points in the subarctic and subtropical regions (green- and yellow-coloured areas in Fig. 1 (b),  
 102 respectively). We also conducted model experiments with the parameters similar to Shigemitsu *et al.* (2012) for the whole  
 103 domain (hereafter ‘Control case’, Table 1). The parameters of all the 3D experimental cases, shown in Table 1, were not  
 104 changed either vertically or temporally. In the parameter-optimised and SST-dependent cases, the parameters were the same  
 105 as the Control case from 1<sup>st</sup> January 1985 to 31<sup>st</sup> December 1996. During the next one year (1997), the simulations were spun-  
 106 up with the optimised or SST-dependent parameters. Then, simulation results on 1<sup>st</sup> Jan. 1998 were used as initial conditions  
 107 for the 1998-year simulations. The parameters values used in the control case were not changed during the 1985-to-1998 period.  
 108 The simulation results for the last year (i.e., 1998) were analysed and compared to observational data of 1998.

## 109 2.2 Satellite and in situ data

110 Global satellite data for 1998 for phytoplankton (i.e. chlorophyll a) were obtained from the Ocean Colour Climate Change  
 111 Initiative, European Space Agency, available online at <http://www.esa-oceancolour-cci.org/>, which utilises the data archives  
 112 of ESAs MERIS/ENVISAT and NASAs SeaWiFS/SeaStar, Aqua/MODIS. The global satellite data which have the horizontal  
 113 resolution of  $0.042^\circ$  were linearly interpolated to the grid (size  $1/10^\circ$  and  $1/6^\circ$ ) in the model domain (Fig. 1 (a)), and the  
 114 nitrogen-converted concentrations of both PL and PS were estimated by a satellite PFT algorithm (Hirata *et al.*, 2011). The  $\mu$ -  
 115 GA cost function was defined from the 1998 monthly averaged PL and PS concentrations. The satellite data of daily temporal  
 116 resolution were not useful due to many regions of missing value. Therefore, we discuss the results for the monthly scale in the  
 117 present study.

118 Satellite data of the 1998 mean SST (horizontal grids of  $0.088^\circ$ ) from the AVHRR Pathfinder Project  
 119 (<http://www.nodc.noaa.gov/SatelliteData/pathfinder4km/>) were also used to conduct our SST-dependent case study using the  
 120 same interpolation procedure as above. The data was linearly interpolated between satellite- and model grids, which could

121 introduce some uncertainty to the satellite data. In addition, the use of the global chlorophyll data in the regional study for the  
122 WNP region could be another error source of the observational data: the previous study (Gregg and Casey, 2004) showed that  
123 the regional Root Mean Square log % errors of the satellite data ranged from 24.7 to 31.6 in the North Pacific.

124 To validate the vertical distribution of the model results, we utilised in situ data of phytoplankton and nutrients in 1998 along  
125 165° E section taken from World Ocean Database 2013 (<https://www.nodc.noaa.gov/OC5/WOD13/>), and at St. KNOT (44° N,  
126 155° E) obtained from the web site (<http://www.mirc.jha.or.jp/CREST/KNOT/>) (Tsurushima et al., 2002).

### 127 2.3 1D NSI-MEM process

128 The 1D NSI-MEM used in Shigemitsu et al. (2012) was employed as an emulator to determine the optimal set of ecosystem  
129 parameters at St. KNOT (44° N, 155° E) and S1 (30° N, 145° E), respectively. We modified the 1D NSI-MEM of Shigemitsu  
130 et al. (2012) by increasing the number of vertical layers to 54 and introducing the vertical advection of the 3D simulation.  
131 Twenty-three of 107 physiological parameters in the NSI-MEM were selected, as shown in Table 2, which were responsible  
132 for PL and PS biomass relevant to the photosynthesis and grazing of zooplanktons. In the previous study, Yoshie et al. (2007)  
133 also suggested that some parameters in the 23 parameters were relatively influential on PS and PL, more than the other  
134 physiological parameters such as those for sinking process of particulate matters (PON, OPAL in Fig. 2). The other parameters  
135 of the NSI-MEM were the same as those in the Control case. The initial (1<sup>st</sup> January 1998) and boundary conditions during the  
136 integration period were applied from those in the 3D model.

### 137 2.4 $\mu$ -GA implementation

138 The  $\mu$ -GA procedure requires a cost function. To define the cost function (Eq. (2)), satellite PFT data were used as reference  
139 values for the  $\mu$ -GA because satellite data have higher temporal and spatial resolution than in situ data. The  $\mu$ -GA procedure  
140 works in such a way that a parameter set of the lowest cost is retained, and then a new parameter set is determined by crossover  
141 and mutation methods using the retained set. An optimised parameter set is finally provided by repeating the process multiple  
142 times.

143 Running the 1D NSI-MEM with the  $\mu$ -GA, the 23 optimal parameters were obtained through the following process:

144 **Step 0** Define a range of parameter values (Table 2) based on previous studies (e.g. Jiang et al., 2003; Fujii et al., 2005;  
145 Yoshie et al., 2007) and prepare 23 model runs being the same number of estimated parameters before running the  $\mu$ -GA.

146 **Step 1** Generate 23 initial random parameter sets using the  $\mu$ -GA.

147 **Step 2** Evaluate the 23 model runs with the different parameter sets using the following cost function:

$$148 \text{ Cost} = \sum_i^I \frac{1}{N_i} \sum_j^{N_i} \frac{1}{\sigma_i^2} (m_{ij} - d_{ij})^2, \quad (2)$$

149 where  $m_i$  is the modelled monthly mean of phytoplankton type  $i$  ( $i = 1$  for PL and 2 for PS) and  $d_i$  is the monthly satellite data  
150 of the type  $i$ . The index  $j$  denotes the number of months ( $N_i$ ) for which satellite data of type  $i$  exists. The assigned weights for  
151 PL and PS were the same low value ( $\sigma_{\text{PL}} = 0.1 \mu\text{mol/l}$  and  $\sigma_{\text{PS}} = 0.1 \mu\text{mol/l}$ ) as some weights used in Shigemitsu et al. (2012).

152 **Step 3** Determine the best parameter set and carry it forward to the next model run (or the next ‘generation’) (elitist strategy).  
153 **Step 4** Choose the remaining 22 sets for re-determination of the best parameter sets (or ‘reproduction’) based on a  
154 deterministic tournament selection strategy (the best parameter set that gave the highest model performance in Step 3 also  
155 competes for its copy in the reproduction). In the tournament selection strategy, the parameter sets are grouped randomly and  
156 adjacent pairs are made to compete. Apply crossover to the winning pairs and generate new parameter sets for the final 22  
157 parameter sets. Two copies of the same set mating for the next generation should be avoided.

158 **Step 5** If the difference between the maximum and minimum cost function values of the model runs becomes smaller than  
159 a threshold value, renew all the parameter sets randomly except for the best-performed set for efficiently escaping from a local  
160 solution; the cost function may have local minimums.

161 **Step 6** Repeat the procedure from Step 2 to Step 5 until the best parameter set is well converged within 2,000 generations  
162 (times) in the present study.

163 The 1D NSI-MEM was used as an emulator to determine ecosystem parameters through the process described above, and the  
164 parameter sets assimilated by the 1D model with the  $\mu$ -GA at St. KNOT and St. S1 were applied to the 3D simulations which  
165 were conducted as the Parameter-optimised case and the SST-dependent case in Table 1.

### 166 3. Results and discussion

#### 167 3.1 1D model

168 The 1D NSI-MEM was employed to determine ecosystem parameters for the 3D-model simulation. The 1D simulation results  
169 (Fig. 3) of Parameter-optimised case (dashed lines) are clearly closer to satellite data (solid lines) than those of Control case  
170 (dotted lines). The cost-function values estimated by the 1D simulations in the optimised case, 1.61 and 0.17 at KNOT and S1,  
171 are also about 8 and 6 times smaller than those in the Control case, 13.55 and 1.11, respectively (not shown).

172 The total biomass (PL+PS) at St. KNOT in the subarctic region is larger than that at St. S1 in the subtropical region. The PS  
173 biomass (yellow lines) is larger than the PL biomass (green lines) at both St. KNOT and St. S1. As for the relative ratio of PL  
174 to the total biomass, the relative ratio at St. KNOT is larger than that at St. S1. These results are consistent with the general  
175 understanding that biomass in the subarctic region is larger than that in the subtropical region, and that the ratio of PL to the  
176 total biomass in the subarctic region is also larger than that in the subtropical region.

177 Seasonal variations in the Parameter-optimised case for the two stations simulated with the satellite data assimilation are also  
178 improved drastically in comparison to the Control case. The seasonal variations of PS and PL at St. KNOT (Fig. 3 (a)) in the  
179 Parameter-optimised case have relatively high concentrations with a winter peak of  $0.63 \times 10^{-3} \text{ molN/m}^3$  and  $0.13 \times 10^{-3} \text{ molN/m}^3$ ,  
180 respectively. In the Control case of PS, however, there is a spring (May) peak of  $0.18 \times 10^{-3} \text{ molN/m}^3$ , and the PL concentration  
181 remains low through the year. At St. S1, the PS seasonal variations tend towards high-concentration in winter and low  
182 concentration from summer to autumn in the Parameter-optimised case, while the PS concentration, in the Control case, in  
183 summer to autumn is higher than that in winter. The parameter-optimisation process by 1D model works well in terms of the

184 seasonal variations of surface phytoplankton.

### 185 3.2 3D model

186 The parameter set **estimated** by the 1D model at St. KNOT and St. S1 were applied to the 3D simulation (Fig. 4). The seasonal  
187 features in the 3D simulation **are generally** similar to those seen in the 1D simulation (i.e. relatively small seasonal variations  
188 of PS biomass in the subarctic region and a relatively high winter biomass in the Parameter-optimised case, **than the Control**  
189 **case**). **At St. KNOT, for instance, there is the smaller difference between the high (575  $\mu\text{molN/m}^3$  in January) and low (398**  
190  **$\mu\text{molN/m}^3$  in October) concentrations in the Parameter-optimised case than the high (568  $\mu\text{molN/m}^3$  in July) and low (59**  
191  **$\mu\text{molN/m}^3$  in January) in the Control case.** The PL biomass features **are also** similar to those of the PS biomass mentioned  
192 above, except that the PL biomass **is** lower in the subtropical region in the Parameter-optimised case than in the **Control** case.  
193 Seasonal peaks of PS and PL biomass also **have** the same features as those in the 1D simulations (i.e. the PS bloom in the  
194 Parameter-optimised case **occurs** from winter to spring (Fig. 4 (c), (g)), but that in the **Control** case occurred in summer (Fig.  
195 4 (b)). **The SST-dependent results are discussed later in Section 3.5.**

196 Higher phytoplankton concentrations ( $> 1000 \mu\text{molN/m}^3$ ) were found in coastal areas throughout the year in the satellite data.  
197 The model could not simulate these high concentrations **in the coastal areas**. This may be due to the inaccuracy of the satellite  
198 data resulting from the high concentrations of dissolved organic material and inorganic suspended matter (e.g. sand, silt and  
199 clay), and/or due to the uncertainty in the model introduced by unaccounted coastal dynamics such as small-scale mixing  
200 processes (e.g., estuary circulation, tidal mixing and wave by local wind forcing). **Any nutrient flux from the seabed was not**  
201 **considered in this study, which also may induce the low-biased phytoplankton biomass close to the coast. Hereafter, we focus**  
202 **on phytoplankton seasonal fluctuation in the pelagic and open ocean in this study.**

203 Lagged (within  $\pm 2$  months) correlation coefficients were calculated for the monthly time series of the surface phytoplankton  
204 concentration between the simulations and satellite data in each grid (Fig. 5). Spatial distributions of the correlation show that  
205 the larger coefficient-value region ( $r > 0.7$ ) of the Parameter-optimised case (Fig. 5 (b)) in  $25^\circ \text{N}$  -  $45^\circ \text{N}$  becomes extended  
206 than that of the Control case (Fig. 5 (a)) by 71 %, though the mean value of the Parameter-optimised case in the north part of  
207  $50^\circ \text{N}$  ( $r=0.18$ ) is smaller than that in the Control case ( $r=0.66$ ). The result is similar in the SST-dependent case (Fig. 5 (c)).  
208 Our parameter estimation significantly improved the simulation result of the horizontal distribution of phytoplankton in the  
209 lower latitude ( $< 45^\circ \text{N}$ ), but not in the region ( $> 50^\circ \text{N}$ ) closer to the coasts.

210 Fig. 6 (a)-(c) shows vertical distributions of total phytoplankton along the  $165^\circ \text{E}$  transect. The parameter optimisation  
211 improves the distributions in that the phytoplankton maximum in the subsurface more deepens than that of Control case (Fig.  
212 6 (b-c)). Parameter-optimised total biomass through the vertical section above 200 m is also closer to the observed data than  
213 the Control case. It is an interesting result because the vertical distribution is improved due to the data-assimilation process  
214 using only surface satellite data. The detailed reason is discussed in Section 3.4. In the nutrients distribution along the  $165^\circ \text{E}$   
215 (Fig. 6 (d) to (i)), the concentrations of Parameter-optimised case (Fig. 6 (f), (i)) are lower than those of Control case (Fig. 6  
216 (e), (h)). The mean values along the transect of nitrate and silicate are  $0.011 \text{ molN/m}^3$  and  $0.025 \text{ molSi/m}^3$ , respectively, in the

217 Parameter-optimised case,  $0.014 \text{ molN/m}^3$  and  $0.034 \text{ molSi/m}^3$  in the Control case, and  $0.012 \text{ molN/m}^3$  and  $0.022 \text{ molSi/m}^3$  in  
218 the observation (Fig. 6 (d), (g)). Parameter-optimised case than Control case is better consistent with the observation, though  
219 the nitrate observed value is higher than the simulations in the surface ( $< 80 \text{ m}$ ) and subarctic ( $> 42^\circ \text{ N}$ ) region. While nitrate  
220 is not effective nutrient compared with iron and silicate for phytoplankton's photosynthesis in the subarctic region (the detail  
221 is also mentioned in Section 3.4), the data-assimilation process improves even the nutrient field in addition to the phytoplankton  
222 field.

223 As for the temperature and salinity along the vertical section (Fig. 7), the physical field used by the model simulations is well  
224 reconstructed in terms of mixed layer depth and transition from the subarctic and the subtropical regions. Judging from the  
225 temperature and salinity distributions in the subarctic region ( $> 42^\circ \text{ N}$ ), the water columns are well mixed vertically both in  
226 the observation and the simulation, and intensely stratified in the subtropical region ( $< 36^\circ \text{ N}$ ). There is the transition region  
227 ( $36^\circ \text{ N} - 40^\circ \text{ N}$ ) of temperature between the subtropical and the subarctic.

### 228 3.3 Amplitude and phase of seasonal variation of phytoplankton

229 At the St. KNOT and St. S1 stations, seasonal variation in total phytoplankton concentrations in the Parameter-optimised case  
230 were generally better reproduced to those in the satellite data than those in the Control case (Fig. 8), though the correlation  
231 coefficients were small in the high latitude region (Fig. 5 (b)). At St. KNOT (Fig. 8 (a)), the phytoplankton bloom in the  
232 Parameter-optimised case occurs in winter, and the phytoplankton bloom in the Control case occurs in summer in an anti-phase  
233 to that of the satellite. At St. S1 (Fig. 8 (b)), the timing of maximum phytoplankton concentration in the Parameter-optimised  
234 case matches that of the satellite in spite of its larger seasonal variation amplitude compared to those in the satellite data and  
235 the Control case. The seasonal variations of the PS and PL concentrations are similar to the total phytoplankton concentrations  
236 (not shown) in both cases.

237 Figure 9 shows comparisons of the amplitude and the phase of seasonal variations between three model cases (Control,  
238 Parameter-optimised and SST-dependent) and the satellite data. The radius shows the amplitude of seasonal variation for each  
239 of the modelled cases relative to the satellite data, and the angle from the x-axis shows the maximum concentration time lag  
240 for each of the model cases (i.e. the point (1, 0) shown as 'True' is a perfect match to the satellite data). At St. KNOT, the  
241 Parameter-optimised case (blue solid vector) exhibits the phase closest to the satellite data among the three modelled cases.  
242 The ratios of the amplitudes to the satellite data were as follows: 1.00 for the Parameter-optimised case (blue solid vector);  
243 1.08 for the SST-dependent case (yellow solid vector) and 1.24 for the Control case (orange solid vector). The timings of the  
244 maximum concentration were as follows: a two-month delay for the Parameter-optimised case (blue solid vector); a three-  
245 month delay for the SST-dependent case and a six month delay (anti-phase) for the Control case. The timing of the Parameter-  
246 optimised case at St. S1 (blue broken vector) was improved, though its seasonal amplitude was not.

247 Optimisation of the physiological parameters by assimilating the satellite data at the two stations improved the seasonal  
248 variations of the phytoplankton concentrations such as the timing of the maximum concentration and the seasonal amplitude  
249 of the WNP region.

### 250 3.4 Vertical distributions of phytoplankton and nutrients concentrations at St. KNOT

251 The model-simulated vertical distributions of phytoplankton, nitrate and silicate concentrations at St. KNOT on 20<sup>th</sup> July,  
252 1998 were compared with the observed ones on the same day (Fig. 10). The vertical distribution of phytoplankton (Fig. 10 (a))  
253 by 3D simulations in the Parameter-optimised case (solid blue line) is closer to the in situ data (black line) as compared to the  
254 Control case data (solid orange line): the maximum phytoplankton concentration for the Parameter-optimised case and the in  
255 situ data are located in the subsurface around a depth of 50 m, while there is no subsurface maximum in the Control case. The  
256 differences of the biomass between the Parameter-optimised and Control cases become especially larger in the subsurface layer  
257 (40 m to 80 m). Thus, better physiological parameterisation through the data assimilation improves not only the surface  
258 concentration but also the important characteristics of vertical plankton distribution such as the subsurface maximum. This is  
259 an interesting improvement because the physiological parameters are optimised using only surface satellite data.

260 The vertical profile of phytoplankton obtained from the 3D simulation represents the observed ones better than the 1D  
261 simulation, too (Fig. 10 (a)). In addition, the difference in 3D (solid lines) and 1D (dotted lines) is larger in the upper layer (<  
262 80 m) than in the lower layer (> 100 m). Moreover error bars for the 3D simulations, which depict the maximum and minimum  
263 values in  $\pm 0.3^\circ$  around the exact grid of St. KNOT, are also larger in the upper layer than the lower layer. These suggests that  
264 effects of horizontal advection such as mesoscale eddy is important for the daily reconstruction of the profile in the upper layer  
265 as the effects are not included in the 1D model.

266 In the NEMURO, the predecessor version of the NSI-MEM, the amplitude and timing of phytoplankton blooms are  
267 predominantly controlled by the photosynthesis rate (i.e. bottom-up effect of nutrient dependence) rather than the grazing rate  
268 (i.e. top-down effect of zooplanktons) (Hashioka et al., 2013). The former is determined by the smallest limited growth rate of  
269 nitrogen ( $\text{NH}_4$  and  $\text{NO}_3$ ), silicate ( $\text{Si}(\text{OH})_4$ ) and dissolved iron (FeD) (refer to Eq. (A15) and Eq. (A23) in Shigemitsu et al.,  
270 2012). For PS and PL in the Parameter-optimised case and Control case, the dissolved-iron-limited growth rates dominate the  
271 photosynthesis (Fig. 11), while the silicate-growth rate is the second-largest limiting factor for PL (Fig. 11 (b)). The mean iron-  
272 growth rates increase remarkably below a depth of 50 m (e.g., 0.36 to 1.75 and 0.47 to 2.36 in PS and PL, respectively) because  
273 of the parameter optimisation of the potential maximum growth rate ( $V_0$ ) and the affinity ( $A_0$ ) as shown in Table 2. As a result,  
274 the uptake of dissolved iron seems to be accelerated, particularly in the subsurface layer, leading to an increase of the  
275 phytoplankton biomass (Fig. 10 (a)). The larger biomass of phytoplankton may also consume more nitrate and silicate nutrients  
276 resulting in a lower nitrate concentration above a depth of 140 m (Fig. 10 (b)) and silicate (Fig. 10 (c)) as compared to that in  
277 the Control case. The vertical gradients of nitrate and silicate in the Parameter-optimised case are closer to the observed data  
278 than that in the Control case. In the optimised case, nitrate and silicate concentrations are less than the data in situ, both at the  
279 depth of around 50 m ( $0.010 \text{ molN/m}^3$  and  $0.015 \text{ molSi/m}^3$  in the Parameter-optimised case;  $0.015 \text{ molN/m}^3$  and  $0.025$   
280  $\text{molSi/m}^3$  in the observation) and 250 m ( $0.032 \text{ molN/m}^3$  and  $0.075 \text{ molSi/m}^3$ ;  $0.041 \text{ molN/m}^3$  and  $0.095 \text{ molSi/m}^3$ ,  
281 respectively), while those at the depth of around 50 m in the Control case ( $0.017 \text{ molN/m}^3$  and  $0.037 \text{ molSi/m}^3$ ) is higher than  
282 those in the optimised case in which much smaller gradients than the observed gradients are found. In the upper layer, the

283 nutrients are adequately supplied to phytoplankton as a result of the parameter optimisation. As in the lower layer below the  
284 depth of 200 m, the nutrient concentrations are also determined by physical processes in the ocean-basin scale, not only local  
285 biological processes.

286 The change in the dissolved-iron-limited growth rates by optimisation results from the lower concentration of dissolved iron  
287 in the subarctic area (Fig. 12) because of the greater consumption of FeD by the phytoplankton compared to that in the Control  
288 case. In the Parameter-optimised case (Fig. 12 (b)), the low concentration of dissolved iron in the subarctic region (north of  
289 40° N) is consistent with the conception of a HNLC region in the North Pacific Ocean (Moore et al., 2013).

### 290 3.5 Physiological parameter changes with ambient conditions

291 The SST-dependent case (i.e. smoothed changing parameters) was compared to the Parameter-optimised case (i.e. boundary-  
292 gap parameters). The horizontal distribution of the PS and PL concentrations in the SST-dependent case were not significantly  
293 different from those in the Parameter-optimised case (Fig. 4) except in two regions—the western region of low latitude (15°  
294 N to 25° N and 120° E to 150° E during January and April in Fig. 4 (h)), and the region adjacent to the Kuroshio Extension  
295 (around 40° N during July to October in Fig. 4 (h)). The former exception was due to the extrapolation of parameters with high  
296 SST and the latter was due to smoothing of parameters between the St. KNOT and St. S1 stations. The simulated seasonal  
297 variations of phytoplankton concentration in the SST-dependent case was slightly worse than those in the Parameter-optimised  
298 case at the two stations (Fig. 9). The ratios of the seasonal amplitudes at St. S1, for instance, were 2.33 for the Parameter-  
299 optimised case and 2.39 for the SST-dependent case. The maximum concentration for the both cases were found in the same  
300 month (March) as that for the satellite data (they overlap each other on the no-lagged x-axis in Fig. 9). However, a smoothed  
301 set of parameters dependent on the SST prevents the artificial gap of the parameter value at the fixed boundary between the  
302 two provinces.

303 Physiological parameters represented in ecosystem models change with the surrounding conditions (e.g. nutrient abundance,  
304 light intensity and SST) in the real ocean. Smith and Yamanaka (2007) and Smith et al. (2009) suggest the significance of  
305 photo-acclimation and nutrient affinity acclimation. Phytoplankton cells change their traits (e.g. nutrient channel, enzyme) in  
306 response to ambient nutrient concentrations, and typically large (small) cells adapt to low (high) light and high (low) nutrient  
307 concentrations (Smith et al., 2015). In the NSI-MEM, the effect of nutrient-uptake responses by plankton acclimated to  
308 different ambient nutrient conditions is applied as an OU kinetic formulation, but the effect of photo-acclimation has not yet  
309 been introduced. As the first trial of the 3D NSI-MEM, the effect of the physiological parameter change with time was not  
310 included in this study, due to the difficulties and complexities of the scientific interpretation (Schartau et al., 2016). However,  
311 the effects of seasonal variation on the physiological parameters seems significant; thus, the variation effects will be added to  
312 the data assimilation process.

## 313 4 Conclusions

314 We extended a LTL marine ecosystem model, NSI-MEM, into a 3D coupled OGCM. We also used a data assimilation  
315 approach with a  $\mu$ -GA for two different PFTs in the WNP region: non-diatom PS and PL. Twenty-three parameters in the NSI-  
316 MEM were estimated using a 1D emulator with a  $\mu$ -GA parameter-optimisation procedure, referred to as satellite data. By  
317 applying the optimised parameters to the 3D NSI-MEM Parameter-optimised case, the model performances were improved in  
318 terms of the seasonal variations of phytoplankton biomass, including the timing of the plankton bloom in the surface layer,  
319 compared to those using prior parameter values (**Control** case). The vertical distribution of phytoplankton such as in the  
320 subsurface maximum layer were also improved due to the easier-to-use of dissolved iron via the parameter changes, compared  
321 to that in the **Control** case.

322 Physiological parameters in this study were systematically determined by a  $\mu$ -GA within the range of those used by numerical  
323 models in previous studies. It would be confirmed whether the values of the physiological parameters are consistent with those  
324 observed in situ and/or explained why each parameter is set to an estimated value based on the various processes (e.g. nutrient  
325 bottom-up, zooplankton top-down and particle sinking processes in the ecosystem model).

456

457 Table

458

459 Table 1. List of experiments

	Experiment name	Content of experiment
1D model experiments	<b>Control</b>	Use the almost same parameters as those in Shigemitsu et al. (2012)
	Parameter-optimised	Optimise the parameters with $\mu$ -GA at St. KNOT and St. S1
3D model experiments	<b>Control</b>	The same as <b>Control</b> of 1-D model but applied to 3-D simulation
	Parameter-optimised	The same as Parameter-optimised of 1-D model but applied to 3-D simulation for two provinces of Fig. 1 (b)
	SST-dependent	The same as Parameter-optimised of 3-D simulation with interpolated parameters at St. KNOT and St. S1 with SST, instead of parameters for two provinces

460

461 **Table 2.** NSI-MEM physiological parameters estimated by the  $\mu$ -GA. Max and Min values prescribe the upper and  
 462 lower bounds of the parameter variations used in the previous studies. St. KNOT and St. S1 indicate optimal  
 463 estimated values in the provinces of Fig. 1 (b) while **Control** values are not optimised parameter values,  
 464 and the values of Shigemitsu et al. (2012) are the parameters of the previous study.

Parameter	Symbol	Min	KNOT	S1	Control	Shigemitsu et al. (2012)	Max	Unit	Sources of Min and Max range
PS Potential maximum growth rate at 0°C	$V_{0,PS}$	0.1	2.7	0.7	0.6	<b>0.6</b>	3.2	/day	Shigemitsu et al. (2012)
PS Potential maximum affinity for $NO_3^-$	$A_{0,NO_3,PS}$	1	454	436	30	<b>282</b>	512	l/molN · s	Shigemitsu et al. (2012)

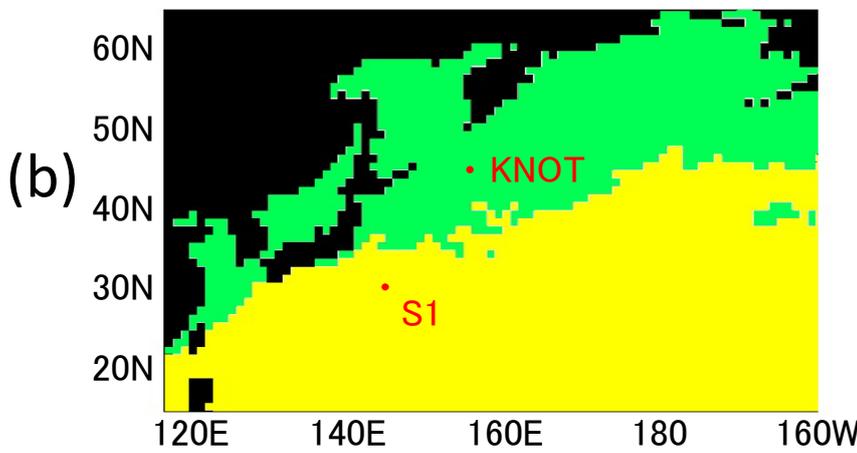

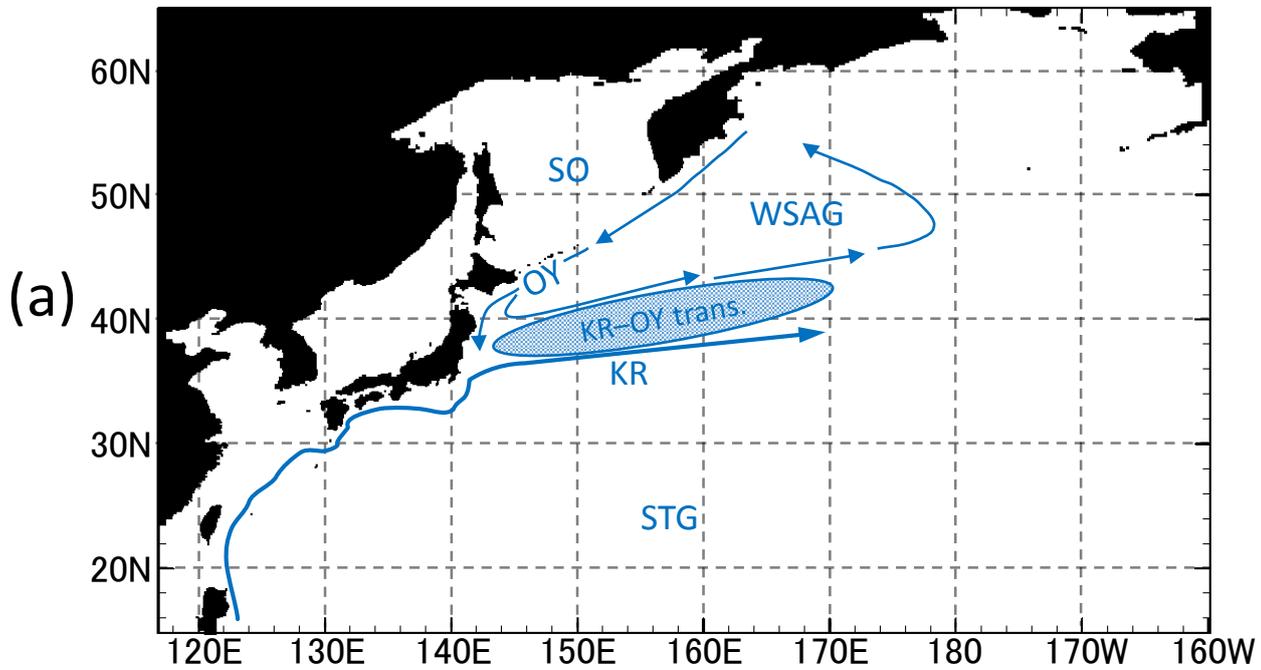

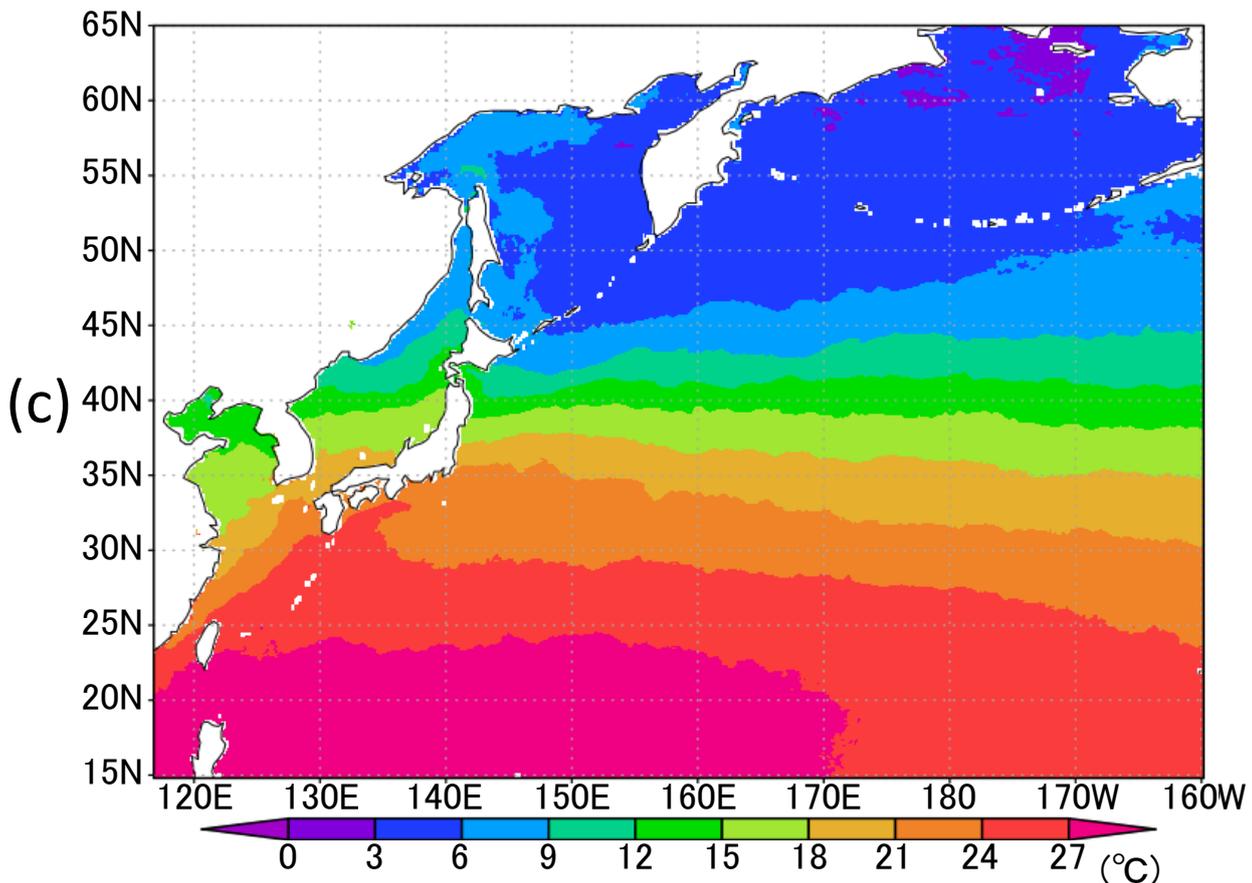

Figure 1. (a) Model domain in the WNP region of the 3D NSI-MEM. Blue arrows and symbols depict a schematic representation of the main circulation features in the WNP (KR: Kuroshio, OY: Oyashio, KR-OY trans.: the Kuroshio–Oyashio transition region, STG: Subtropical Gyre region, WSAG: Western Subarctic Gyre and SO: the sea of Okhotsk). (b) Two classified provinces (subarctic and subtropical regions) based on the dominant phytoplankton species and nutrient limitations by Hashioka et al. (in preparation). Different ecosystem parameters (Table 2) are set for each province in the simulation. (c) Annual mean SST of satellite data used for simulation of SST-dependent physiological parameters (SST-dependent case).

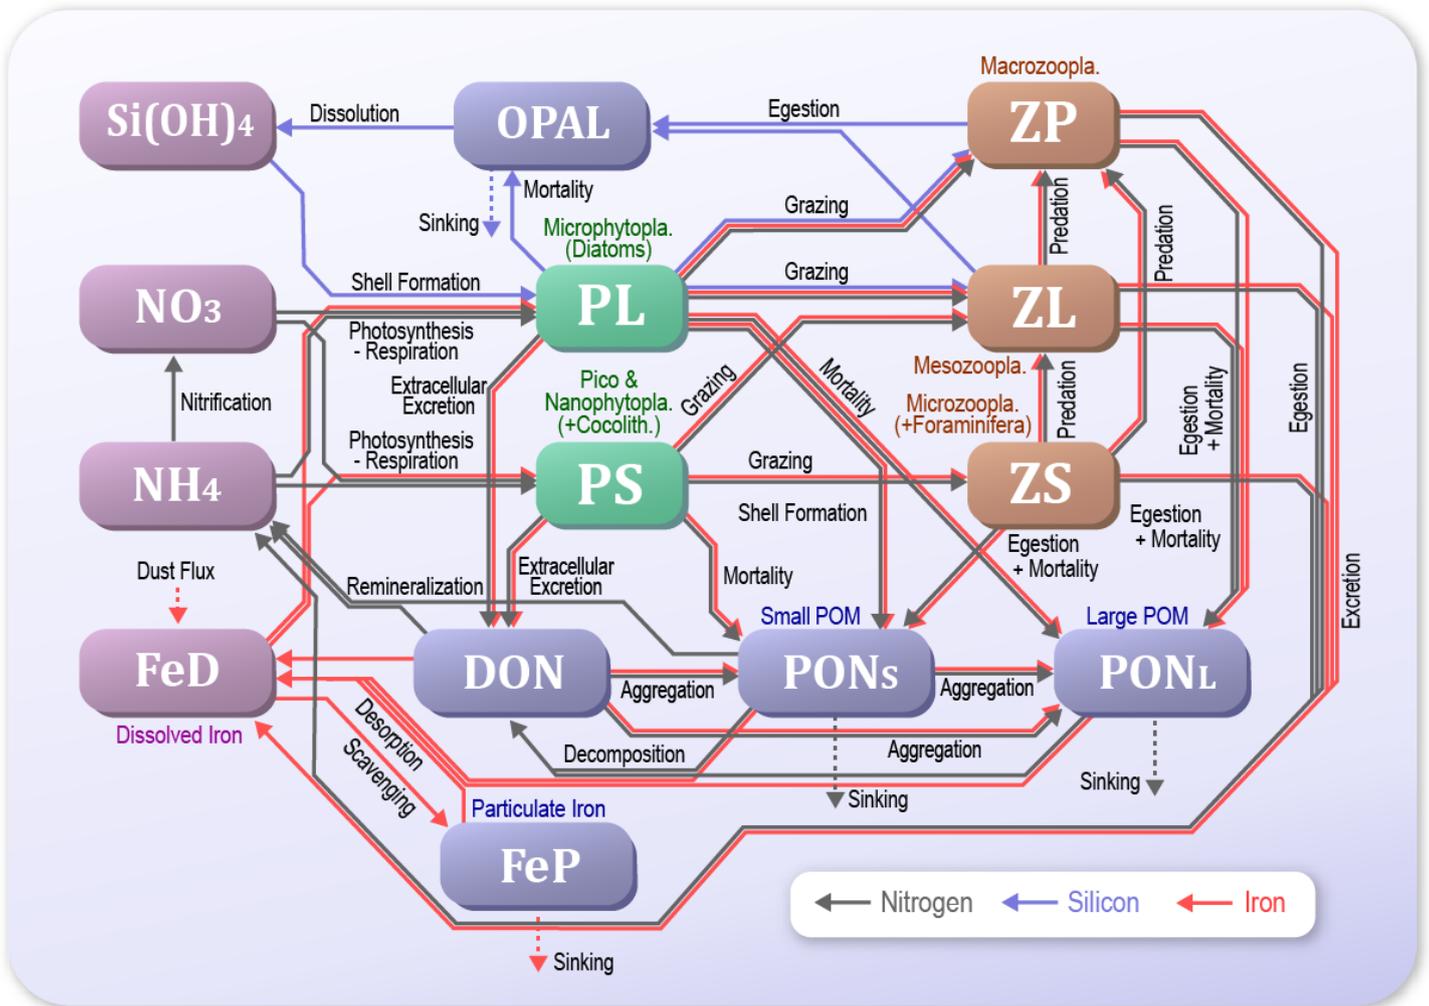

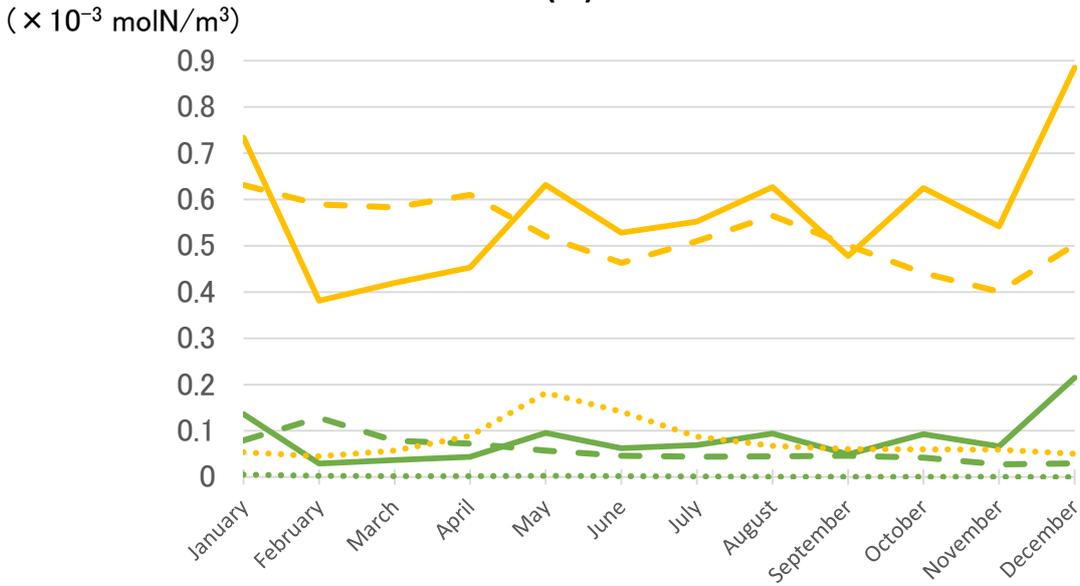

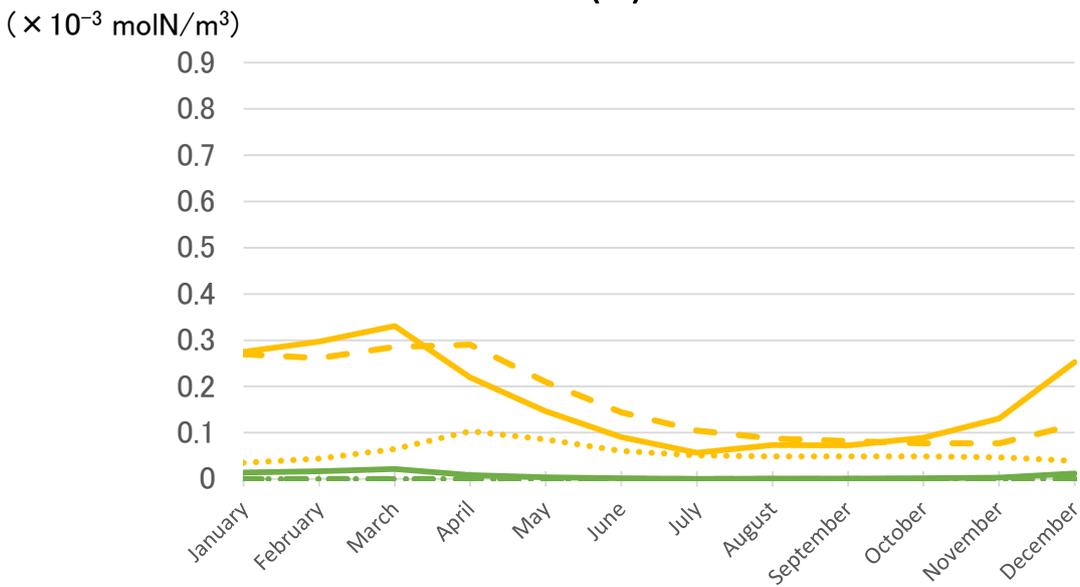

Figure 2. Schematic view of the NSI-MEM interactions among the fourteen components. Green colour boxes and brown boxes indicate phytoplankton and zooplankton, respectively. Blue boxes are particulate/dissolved matters. Violet boxes show nutrients and essential micronutrient.

### (a) KNOT

### (b) S1

PS (small phytoplankton)

PL (large phytoplankton)

— : Satellite data

- - - : Parameter-optimised case

..... : Control case

**Figure 3.** Seasonal variations of surface phytoplankton biomass in the 1D NSI-MEM and satellite data at (a) St. KNOT and (b) St. S1 are shown as typical observational points of the subarctic and the subtropical regions, respectively. **The unit conversion between the simulation data ( $\text{molN/m}^3$ ) and the satellite data ( $\text{gchl-a/m}^3$ ) is referred to as the nitrogen-chlorophyll ratio of PL= 1: 1.59 and PS= 1: 0.636 (Shigemitsu et al., 2012). The same conversion of nitrogen-chlorophyll is used to Fig. 4, Fig. 6, Fig. 8 and Fig. 10.**

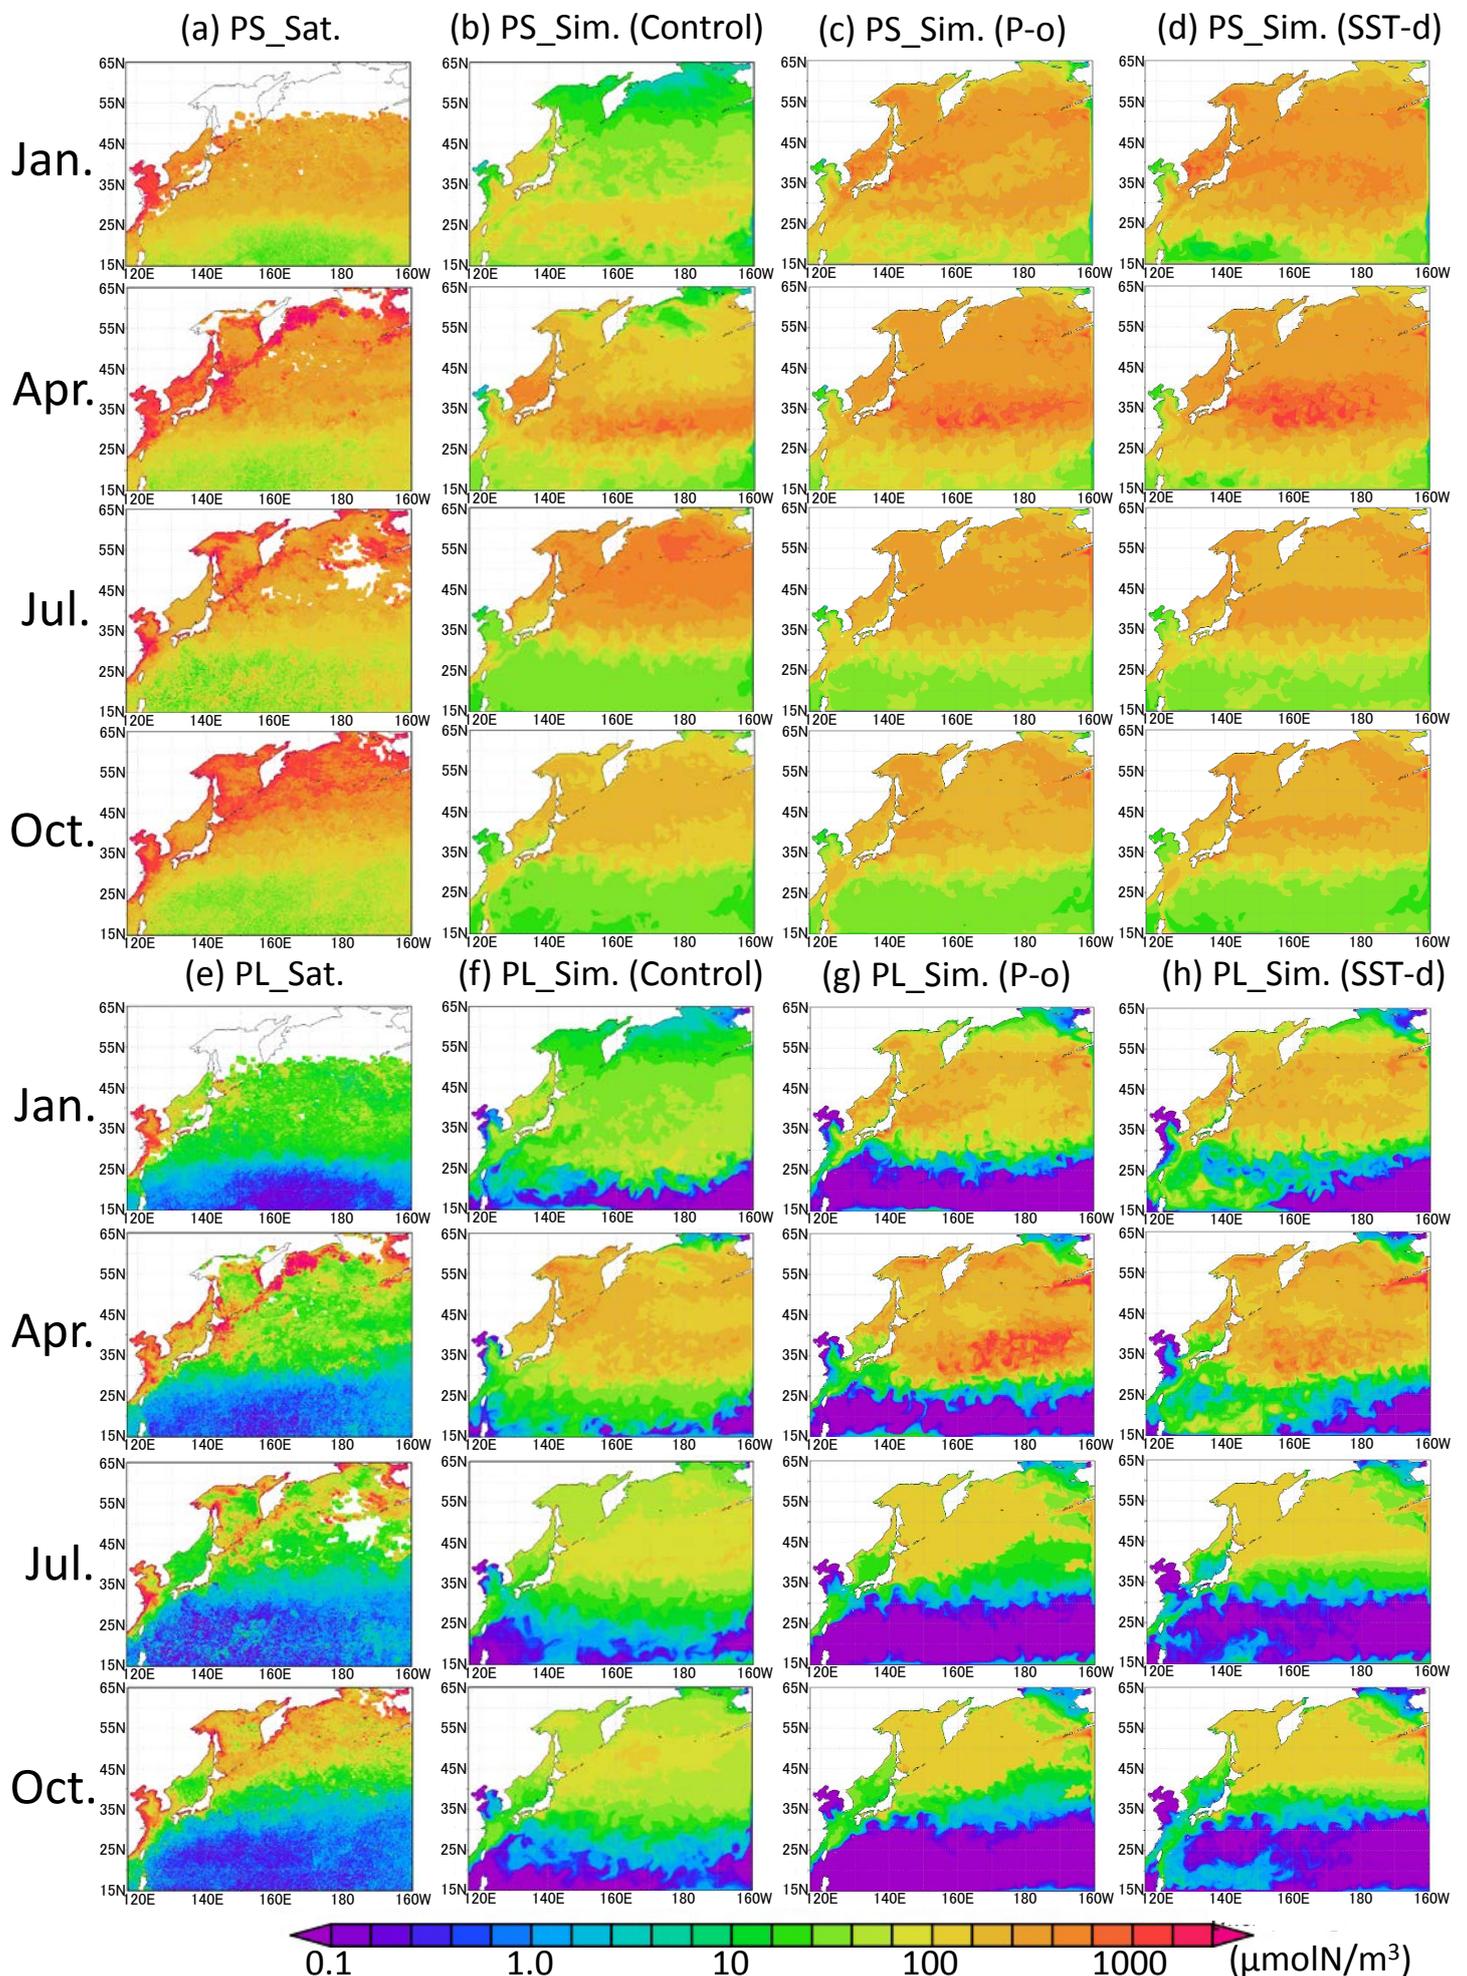

Figure 4. Horizontal distribution of phytoplankton at the surface in 1998. (a) PS (small phytoplankton) from satellites observations, (b) PS in **Control** case, (c) PS in the Parameter-optimised case, and (d) in the SST-dependent case. (e), (f), (g), (h) are the same except for PL (large phytoplankton). Areas without satellite data are left blank.

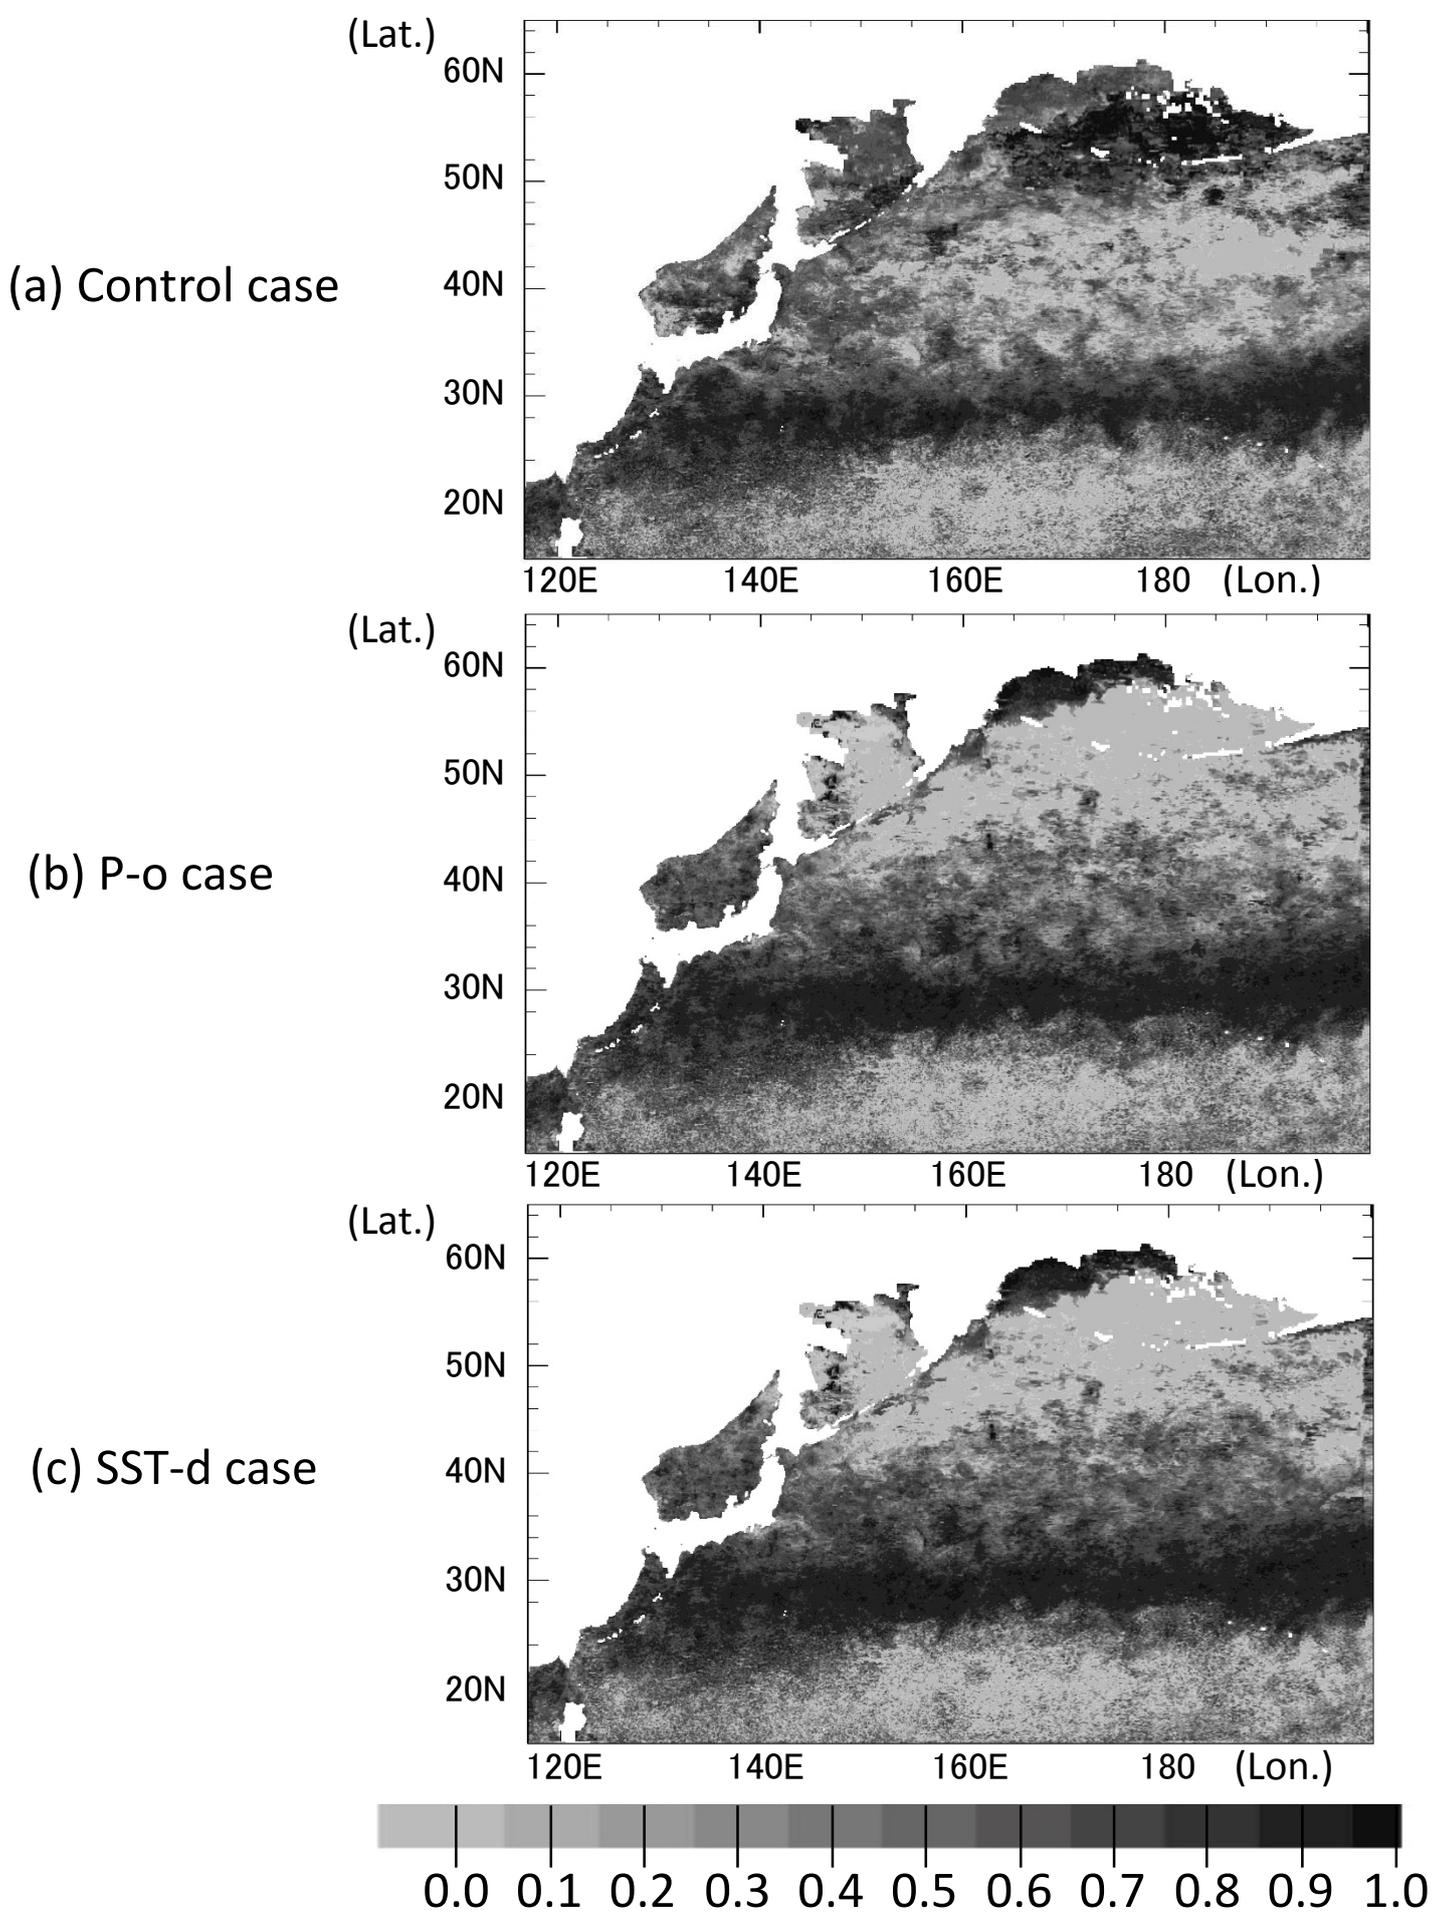

Figure 5. Horizontal distribution of lagged (within  $\pm 2$  months) correlation coefficients were calculated for the monthly time series of phytoplankton (PL+PS) concentration between the simulation and the satellite data in each grid at the surface in 1998. (a) Control case, (b) Parameter-optimised case and (c) SST-dependent case. Areas without satellite data and in the coastal regions where the bottoms are less than 200 m are left blank.

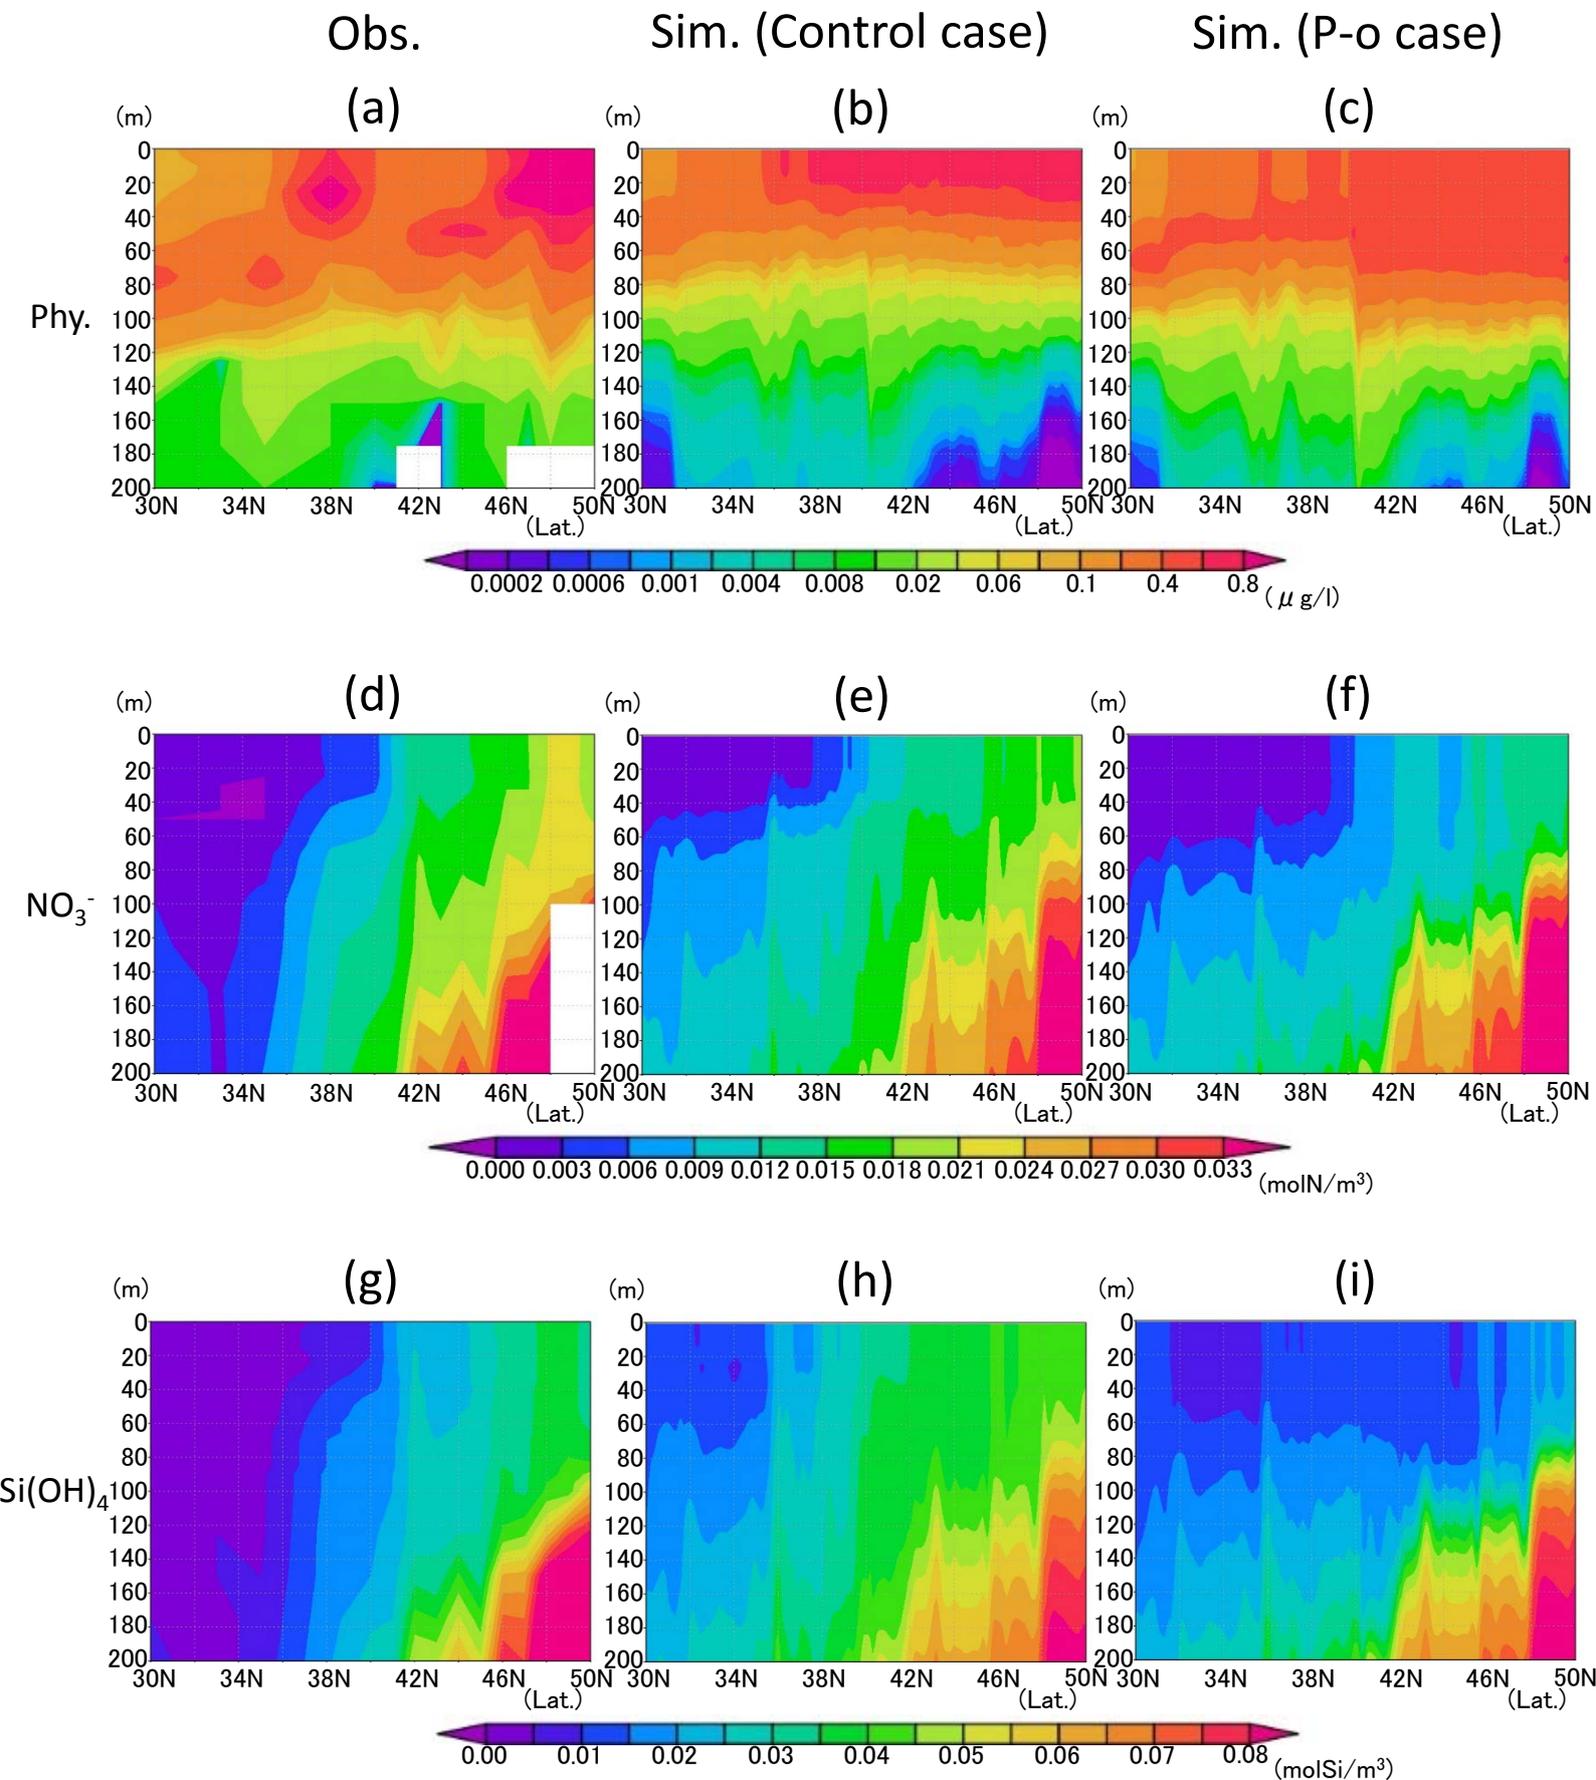

Figure 6. Vertical distribution of phytoplankton (a, b, c), nitrate (d, e, f) and silicate (g, h, i) along the 165° E section in June, 1998. (a, d, g) Data in situ observed during 16<sup>th</sup> June to 21<sup>st</sup> June in 1998 downloaded from World Ocean Database 2013. (b, e, h) Simulation result of Control case in June 1998 mean. (c, f, i) Simulation result of Parameter-optimised case in June 1998 mean. Areas of missing values are left blank.

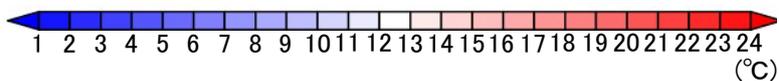

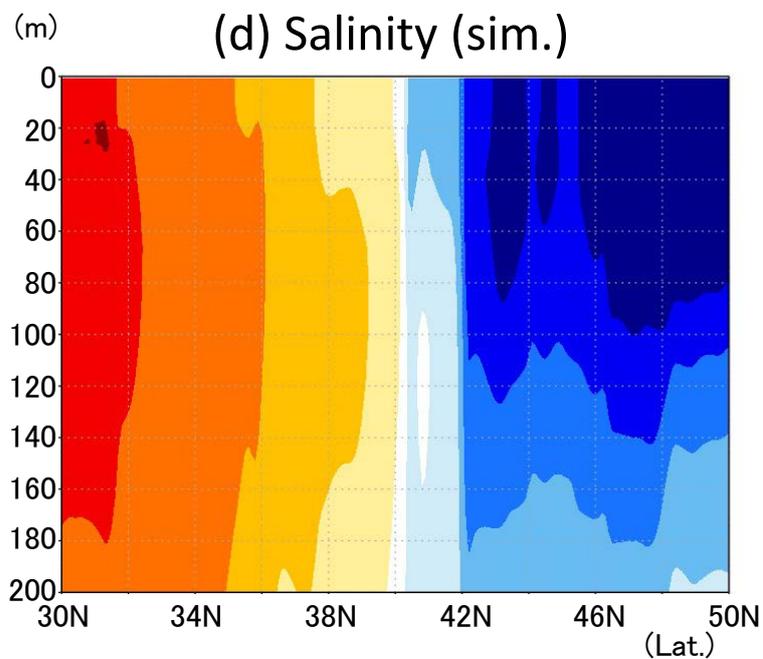

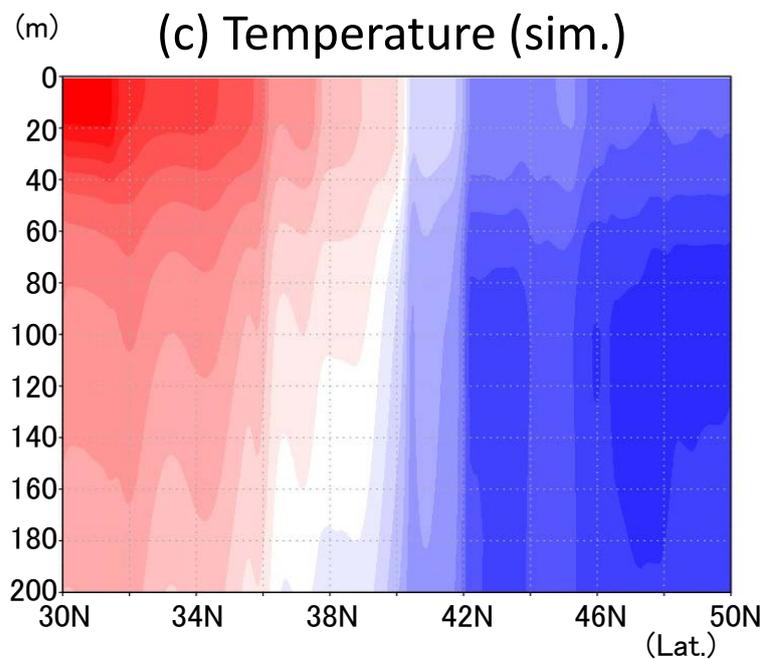

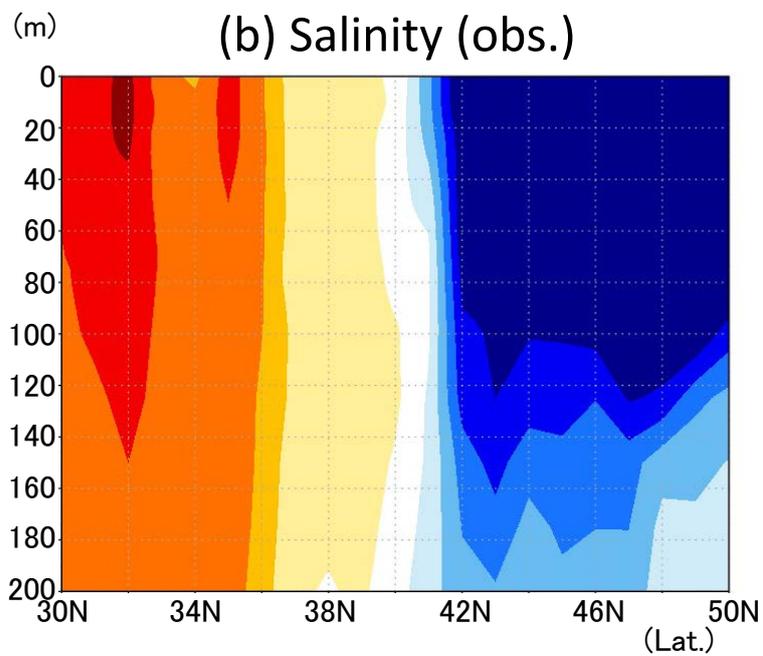

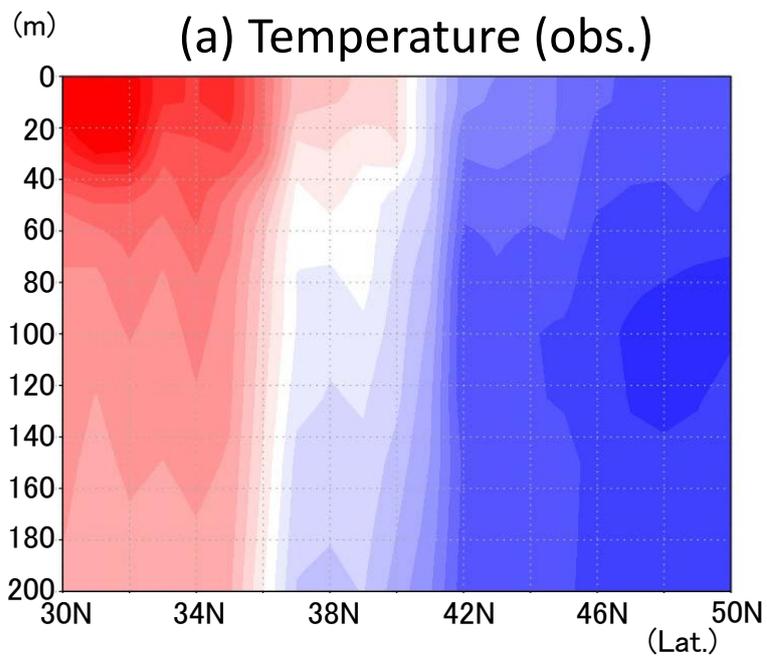

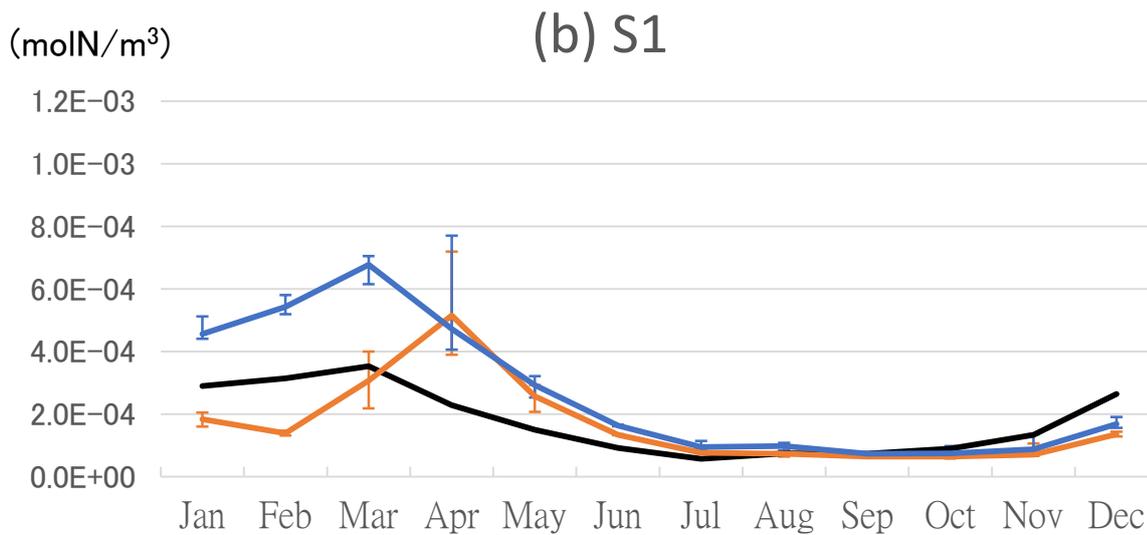

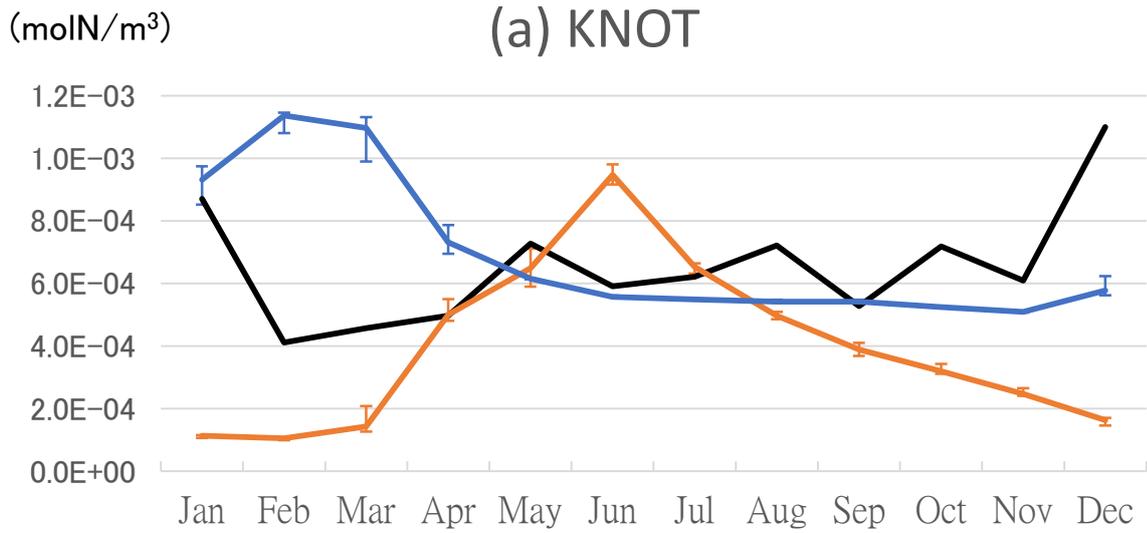

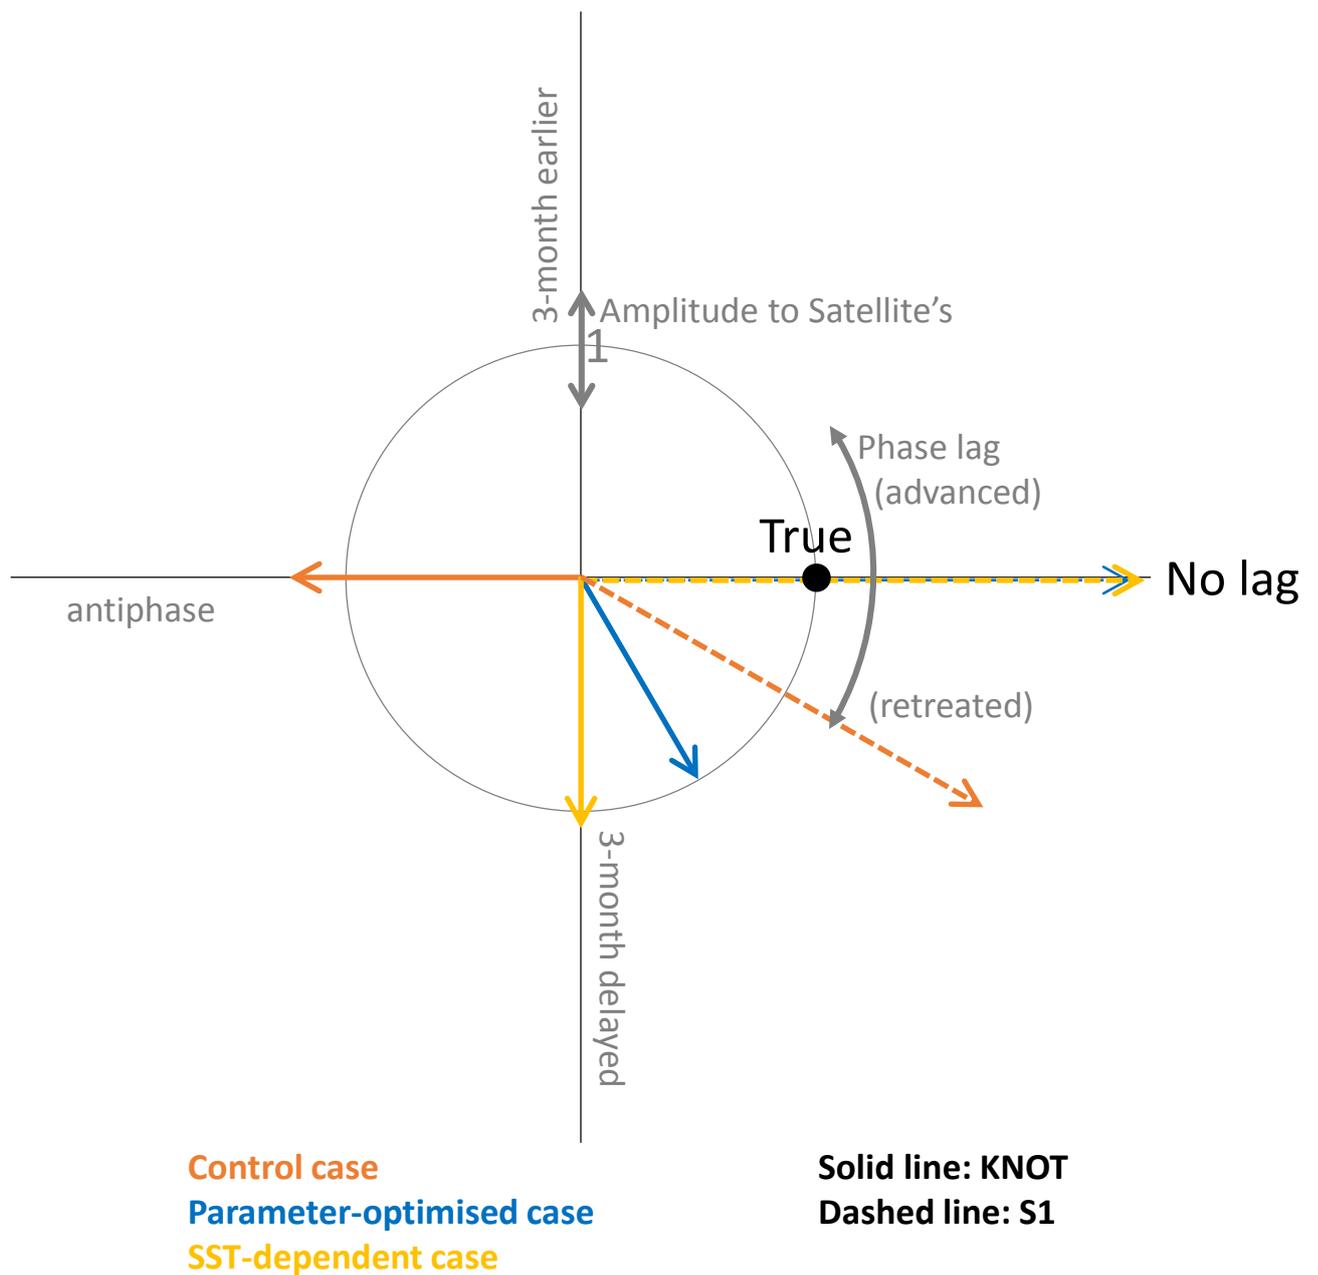

Figure 7. Vertical distribution of temperature (a, c) and salinity (b, d) along the  $165^{\circ}$  E section in June, 1998. (a, b) Data in situ observed during 16<sup>th</sup> June to 21<sup>st</sup> June in 1998 downloaded from World Ocean Database 2013. (c, d) Physical field in June 1998 mean used in the 3D NSI-MEM.

**Satellite**  
**Model (Control case)**  
**Model (Parameter-optimised case)**

**Figure 8.** Time series of phytoplankton (PL+PS) concentration in the 3D NSI-MEM and satellite data at (a) St. KNOT and (b) St. S1. **Error bars of the simulations show the maximum and minimum values in  $\pm 0.3^\circ$  around the grids of St. KNOT and St. S1.**

**Figure 9.** Diagram showing the amplitude and the phase of seasonal variations in the three model cases compared with those in the satellite data. Based on the seasonal variation in the satellite data, the radius indicates the relative amplitude (model/satellite) of seasonal variation for each model case and the angle from the positive x-axis shows the time lag of the maximum concentration for each model case (i.e. the point (1, 0) shown as ‘True’ is the perfect match to the satellite data). The blue dashed line (Parameter-optimised case at St. S1) and yellow dashed line (SST-dependent case at St. S1) overlap on the no-lagged x-axis.

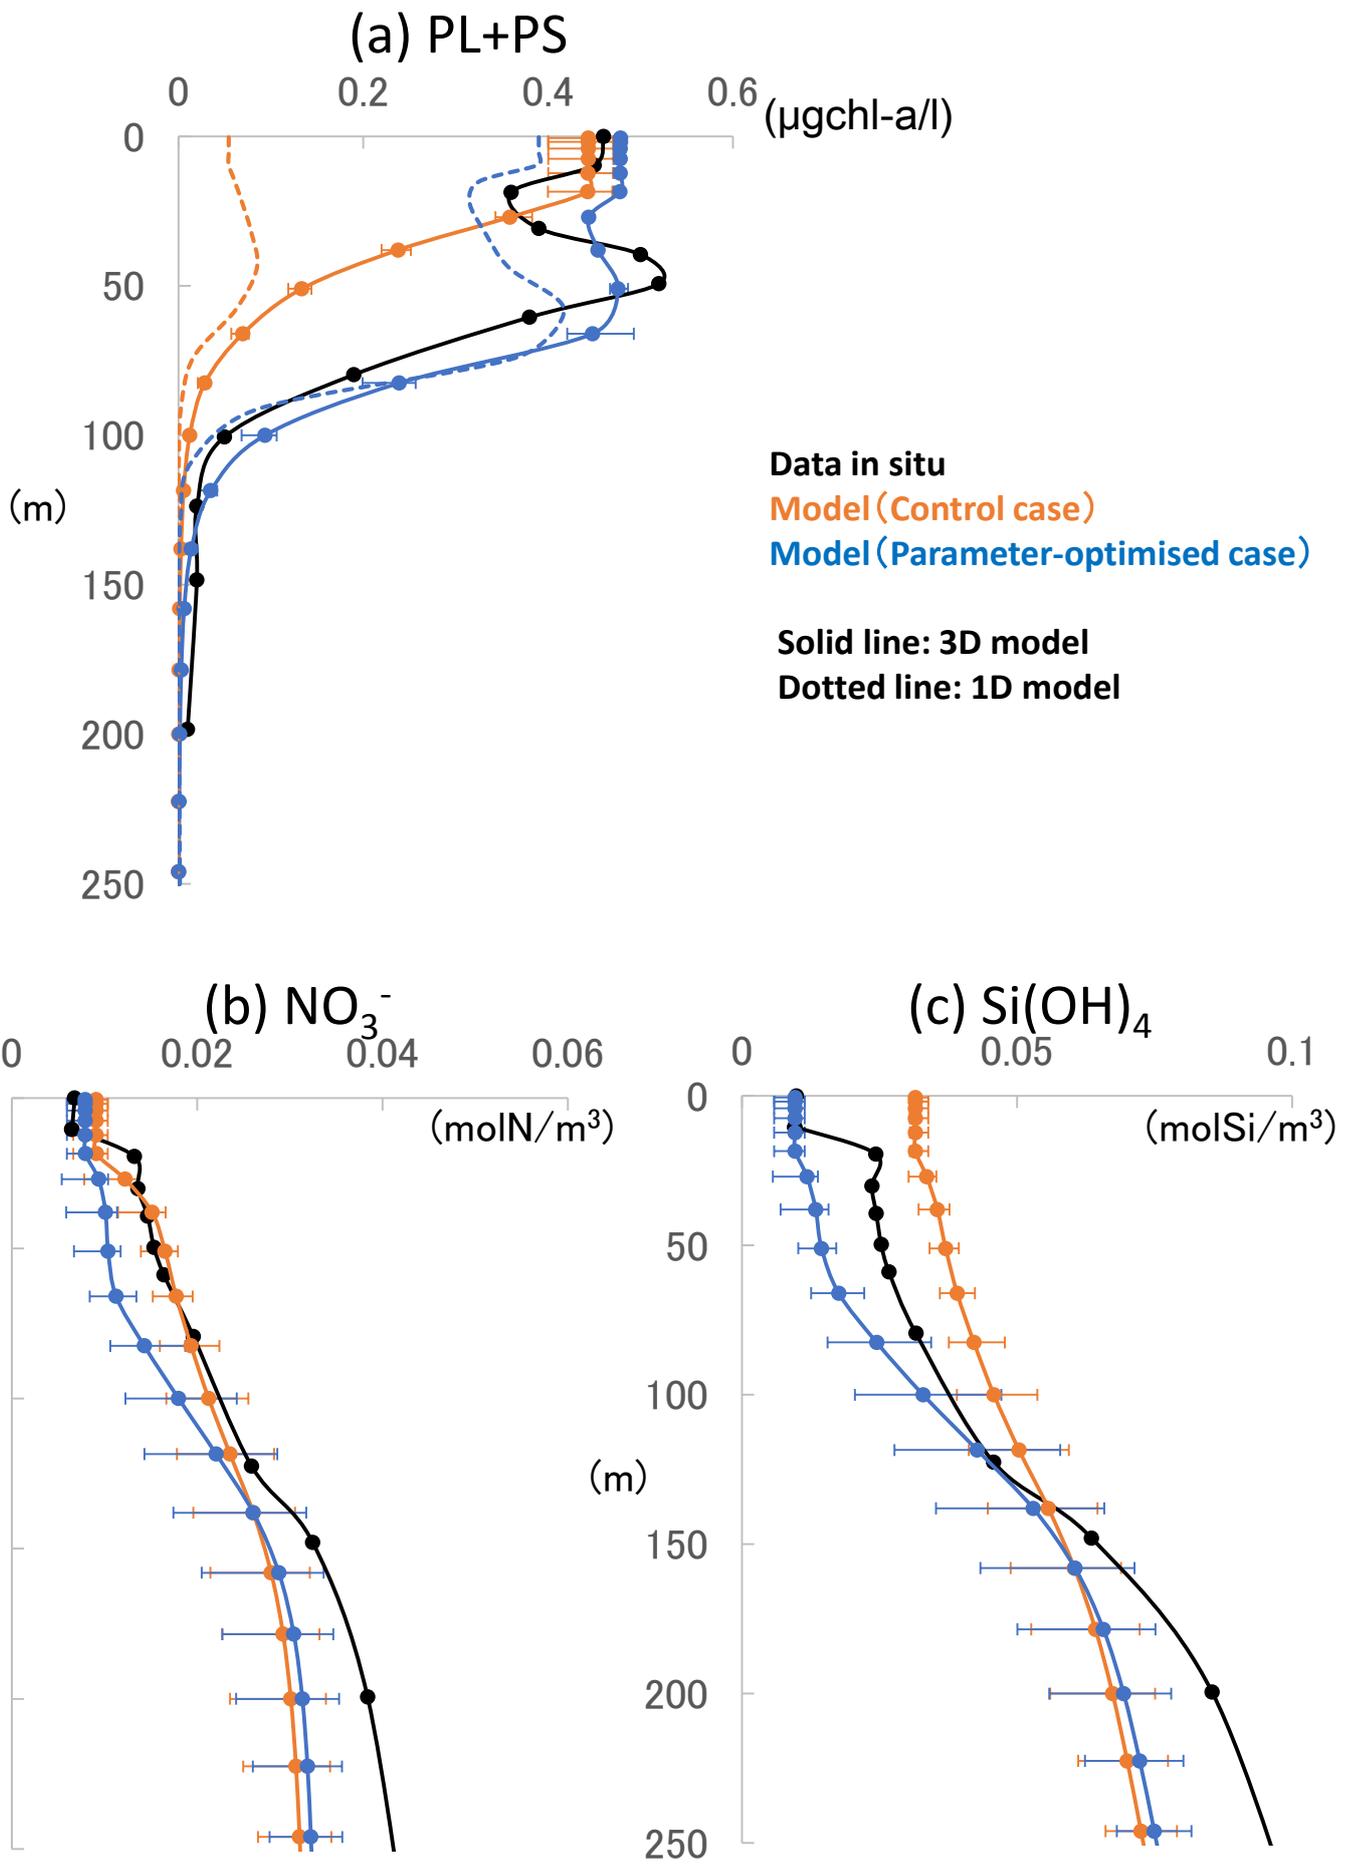

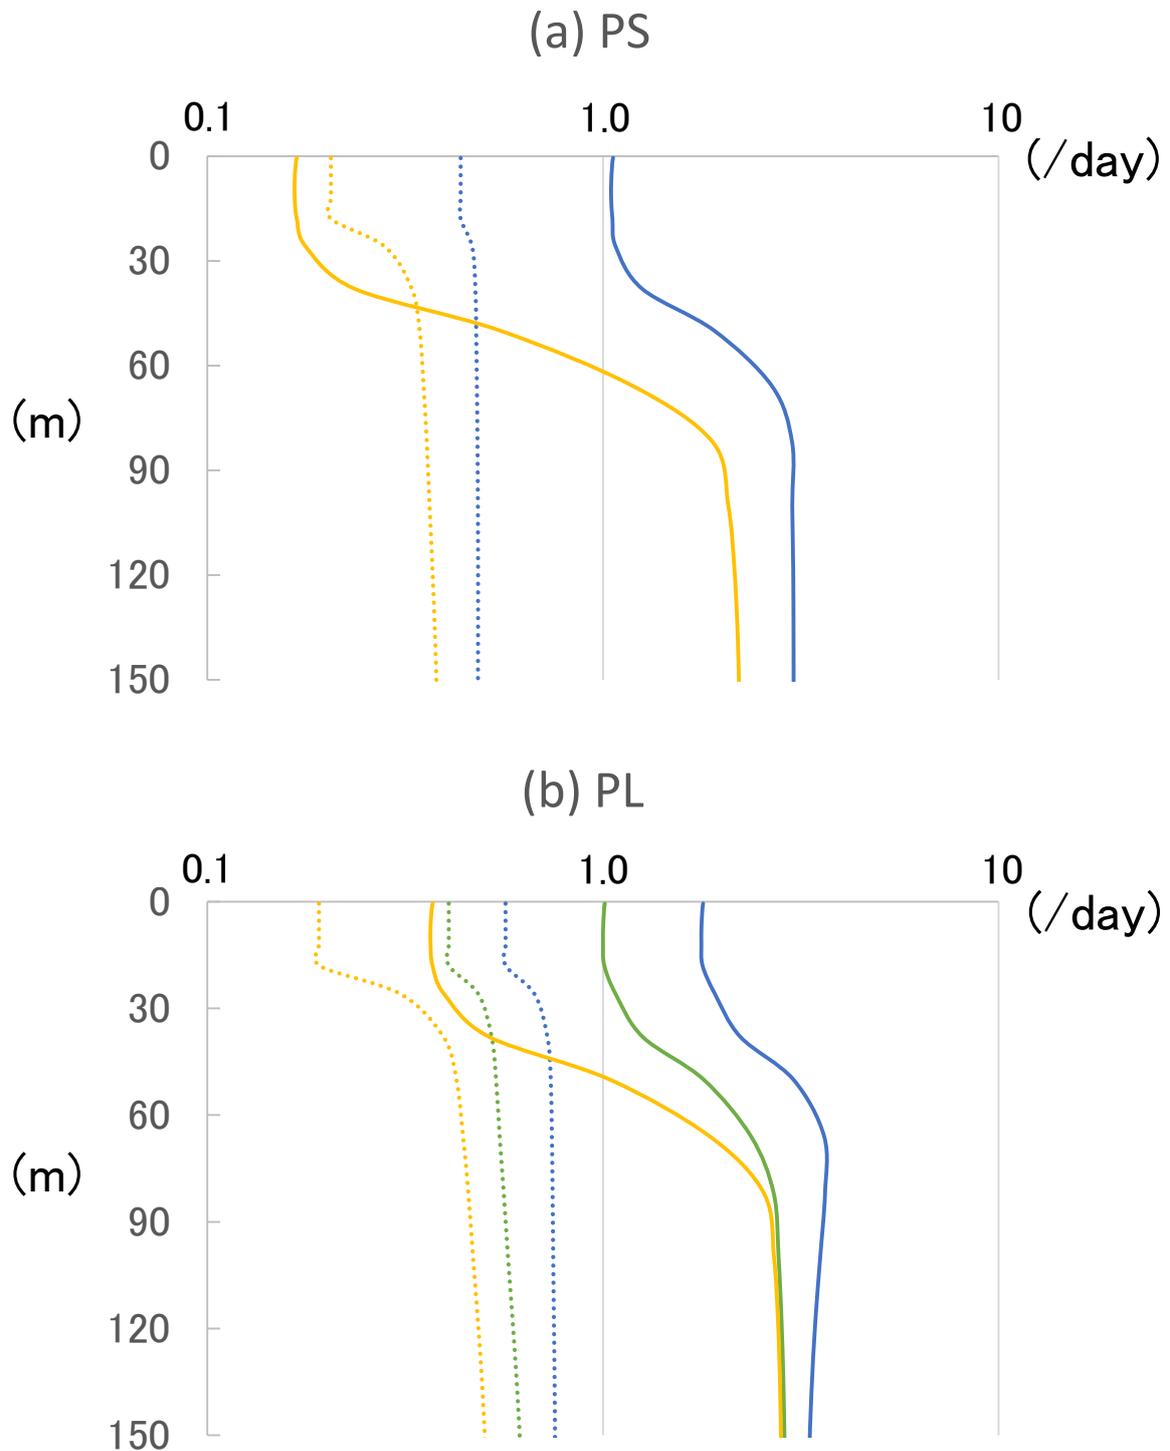

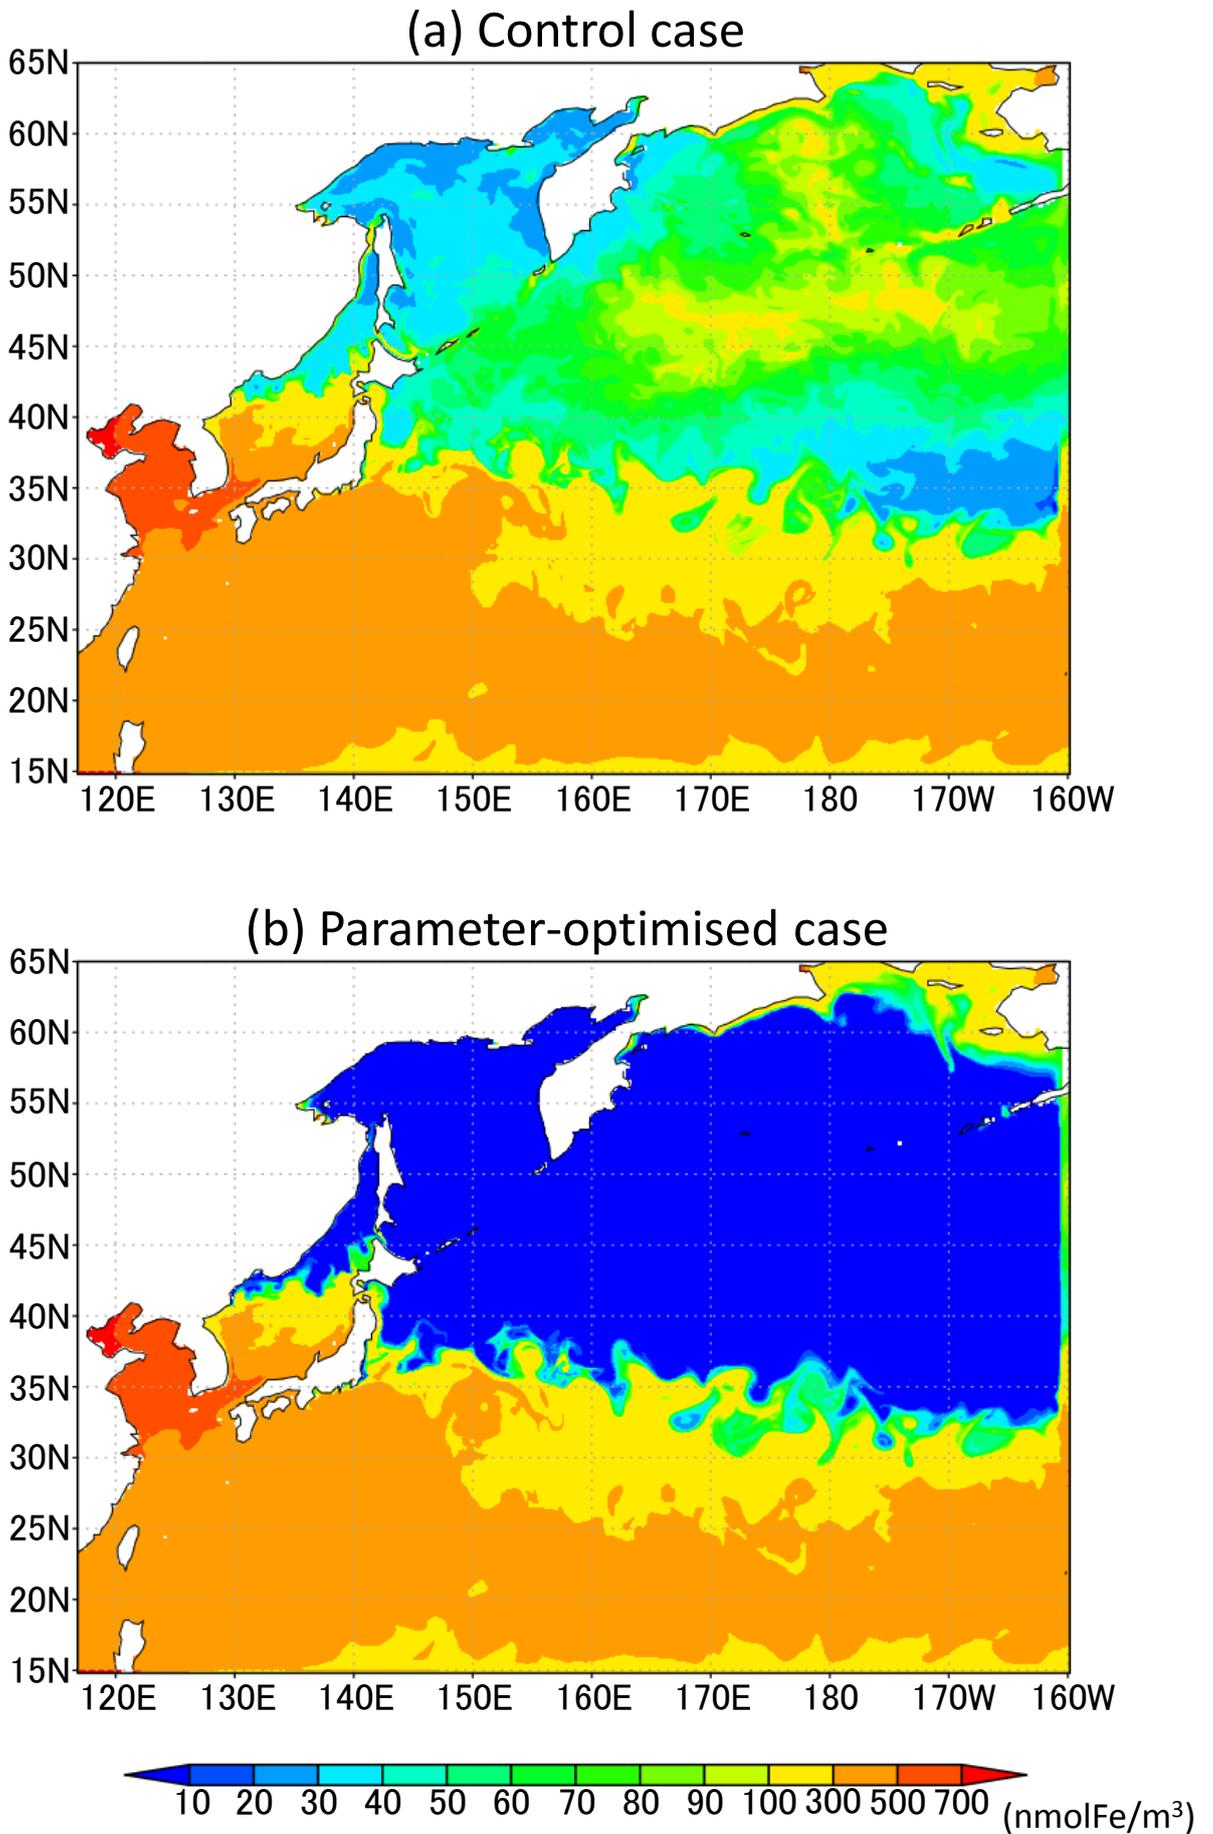

Figure 10. Vertical distributions of (a) phytoplankton (PL+PS), (b) nitrate and (c) silicate concentrations from the 3D model (solid line), 1D model (dotted line) and in situ data at St. KNOT on 20<sup>th</sup> July, 1998. Error bars of the 3D simulations show the same mean as those of Fig. 8.

Limited growth rate by nitrogen  
 Limited growth rate by silicate  
 Limited growth rate by dissolved iron

Solid line: Parameter-optimised case  
 Dotted line: Control case

Figure 11. Vertical distributions of limited growth rates by nitrogen, silicate and dissolved iron simulated from the 3D model of (a) PS and (b) PL at St. KNOT on 20<sup>th</sup> July, 1998.

**Figure 12.** Horizontal distribution of dissolved iron in the surface sea water layer for July 1998; (a) **Control** case and (b) **Parameter-optimised** case.
