Abstract. This study investigated the spatiotemporal variations of activity concentrations in the Sea of Japan (SOJ) of ¹³⁷Cs and these transport process from the North Pacific Ocean to the SOJ through the East China Sea (ECS) during 2012– 2016. The ¹³⁷Cs activity concentrations in the SOJ have been increasing since 2012–2013 and reached a maximum in 2015– 2016 of approximately 3.4 Bq m⁻³, more than twice the pre–Fukushima accident ¹³⁷Cs activity concentration of ~1.5 Bq m⁻³. The ¹³⁴Cs/¹³⁷Cs activity ratios ranged from 0.36 to 0.51 in 2016. After taking into account radioactive decay and ocean mixing, we concluded that these ¹³⁴Cs/¹³⁷Cs activity ratios were evidence that the Fukushima accident caused the increase of the ¹³⁷Cs activity concentrations. In the North Pacific south of Japan (NPSJ), the highest ¹³⁷Cs activities in 2012–2013 were observed in

- water from a depth of 300 m, the potential density anomaly (σ_{θ}) of which corresponded to subtropical mode water (STMW). In the ECS, a clear increase of the ¹³⁷Cs activity concentration started at a depth of 140 m (σ_{θ} = 25.2 kg m⁻³) in April 2013, propagated to the surface layers at depths of roughly 0–50 m, reached a maximum in 2015, and decreased in subsequent years. In the ECS, the Fukushima-derived radiocaesium activity concentration in surface water reached a maximum in 2014–2015, whereas the concentration in the SOJ reached a maximum in 2015–2016. The propagation of Fukushima-derived radiocaesium
- 20 in surface seawater from the ECS into the SOJ therefore required approximately one year. These temporal changes in ¹³⁷Cs activity concentrations and ¹³⁴Cs/¹³⁷Cs activity ratios indicated that part of the ¹³⁷Cs and ¹³⁴Cs derived from the Fukushima accident (FNPP1-derived ¹³⁷Cs and ¹³⁴Cs) was transported within several years to the ECS and then to the SOJ via STMW from the NPSJ. The integrated amount of FNPP1-derived ¹³⁷Cs that entered the SOJ before 2016 was estimated to be 0.21 ± 0.01 PBq, 5.0 % of the estimated total amount of FNPP1-derived ¹³⁷Cs in the STMW. The integrated amount of FNPP1-derived
- ¹³⁷Cs that returned to the North Pacific Ocean through the Tsugaru Strait was estimated to be 0.09 ± 0.01 Bq, 43 % of the total amount of FNPP1-derived ¹³⁷Cs transported to the SOJ and 2.1 % of the estimated total amount of FNPP1-derived ¹³⁷Cs in the STMW.

1 Introduction

The Fukushima Daiichi Nuclear Power Plant (FNPP1) accident in March 2011 released radiocaesium (¹³⁷Cs, half-life 30.07 30 yr, and ¹³⁴ Cs, half-life 2.06 yr) directly to the air and also directly discharged contaminated water to the ocean, primarily in March and April 2011. Eighty per cent of the radiocaesium released to the atmosphere was deposited on the surface of the ocean (Aoyama et al., 2016a; Buesseler et al., 2016; Hirose, 2016; Tsumune et al., 2013). The ¹³⁷Cs activity concentration in the surface seawater of the North Pacific Ocean after the FNPP1 accident ranged from a few Bq m⁻³ to about 1 kBq m⁻³ (e.g., Aoyama et al., 2012, 2013; Honda et al., 2012; Kaeriyama et al., 2013, 2014). A basin-scale assessment indicated that the

- 35 FNPP1-derived radiocaesium was confined to a region from 25°N to 50°N and from 135°E to 135°W in April and May 2011 (e.g., Aoyama et al., 2013; 2016a; Inomata et al., 2016; Tsubono et al., 2016). At latitudes as far north as ~40°N, the radiocaesium was transported eastwards at a rate of approximately 8 cm s⁻¹ by North Pacific currents such as the Kuroshio and Kuroshio Extension. It reached 165°E in July–September 2011 and the 180th meridian in January–March 2012 (Aoyama et al., 2012, 2013). FNPP1-derived radiocaesium was also found further south in the North Pacific Ocean, where there was a
- 40 subsurface maximum of 137 Cs at a depth of \sim 300 m (Kaeriyama et al., 2013, 2014, 2016; Kumamoto et al., 2013, 2017). Similar

subsurface maxima of ¹³⁷Cs were found in subtropical mode water (STMW; potential water density anomaly $[\sigma_{\theta}]$ 25.0–25.6 kg m⁻³; Masuzawa, 1969) and central mode water (CMW; $\sigma_{\theta} = 26.0-26.5$ kg m⁻³) (Aoyama et al., 2016a; Kumamoto et al., 2014, 2015). Aeolian ¹³⁷Cs deposited south of the Kuroshio Extension was apparently subducted into the STMW and transported southwards within 10 months after the FNPP1 accident. Rossi et al. (2013) have reported that simulated FNPP1-

- 5 derived ¹³⁷Cs penetrated into the ocean interior via intense subduction and vertical mixing during the winter in the region of mode water formation as described by Oka and Qiu (2012). Kamidaira et al. (2018) have also reported that their model simulation reproduced relatively high ¹³⁷Cs activity concentration below the mixed layer. Their simulation indicated that about 43 % of FNPP1-derived ¹³⁷Cs was transported below the mixed layer by eddy processes.
- Before the FNPP1 accident, ¹³⁷Cs was injected into the environment as a result of the large-scale atmospheric nuclear 10 weapons tests that occurred in the late 1950s and early 1960s and the Chernobyl accident in 1986. Caesium-137 was therefore present in the North Pacific Ocean and its marginal seas (Aoyama et al., 2006; Inomata et al., 2009, 2012). Russia and the former USSR dumped radioactive wastes into the northern part of the Sea of Japan (SOJ), although this dumping caused no significant increase in the activity concentrations of ¹³⁷Cs (Miyao et al., 1998). During the 2000s, the distribution of ¹³⁷Cs activity concentrations was almost homogeneous in the Pacific Ocean, although the activities were relatively high in the
- western part of the subtropical gyre in the North Pacific Ocean (>2 Bq m⁻³) and the South Pacific Ocean (>1.5 Bq m⁻³) 15 (Aoyama et al., 2012). There have hence been two sources of ¹³⁷Cs in the North Pacific Ocean and its marginal seas, the ¹³⁷Cs released by global fallout (global fallout-derived ¹³⁷Cs) and FNPP1-derived ¹³⁷Cs. In contrast, the ¹³⁴Cs derived from global fallout and the Chernobyl accident had decayed to below the limit of detection by 1993 because of its two-year half-life (Miyao et al., 1998). Therefore, ¹³⁴Cs has been a satisfactory chemical tracer of the radiocaesium derived from the FNPP1 accident.
- 20 Atmospheric deposition of radiocaesium after the FNPP1 accident caused activity concentrations of radiocaesium in the north-eastern SOJ in May 2011 (1.5–2.8 Bq m⁻³) to be approximately 1–2 times the activity concentrations before the FNPP1 accident (~1.5 Bq m⁻³) (Fig. 1). By the end of 2011, the ¹³⁷Cs activity concentrations in the north-eastern part of the SOJ had decreased rapidly to almost the same levels as before the FNPP1 accident (Inoue et al., 2012).

The SOJ, the main region of interest in this study, is located between the Eurasian continent and the Japanese archipelago. It has an area of 1×10^6 km² and a mean depth of 1.67 km (Menard and Smith, 1966). The south-western SOJ is connected to 25 the East China Sea (ECS) through the Tsushima Straits, and the north-eastern SOJ is connected to the North Pacific Ocean through the Tsugaru Straits. Warm, saline seawater passes through the Tsushima Strait via the Tsushima Warm Current (TWC). This current splits into two separate currents. One is the nearshore current that flows along the west coast of Honshu Island, Japan. Some of this water passes through the Tsugaru Strait and into the Pacific Ocean. The remainder is transported to the

- north and passes through the Soya Strait into the Sea of Okhotsk. The other current flows north of the Korean Peninsula. This 30 current meets the North Korean Cold Current, which is an extension of the Liman Cold Current. This northward-flowing warm, subtropical water meets southward-flowing cold, subarctic SOJ waters to form the Polar Front at approximately 40°N. The SOJ is therefore divided largely into two regions (Prants et al., 2015). The current system in and around the SOJ should be taken into consideration when assessing the spatiotemporal variations of radiocaesium derived from global fallout and the 35 FNPP1 accident.

40

The purposes of this study were to 1) investigate the spatiotemporal variations of activity concentrations in the SOJ of ¹³⁷Cs released as a result of the FNPP1 accident, 2) investigate the processes responsible for transport of radiocaesium from the North Pacific Ocean to the SOJ through the East China Sea, and 3) estimate the amount of FNPP1-derived ¹³⁷Cs transported into the SOJ through the Tsushima Strait as well as the amount of FNPP1-derived ¹³⁷Cs returned into the North Pacific Ocean through the Tsugaru Strait during 2012-2016 and the uncertainties of these estimates.

2.1 Data sources

After the FNPP1 accident, many radiocaesium measurements were taken in the SOJ and western North Pacific Ocean (Fig. 1). To elucidate the temporal and spatial distributions of the radiocaesium activity concentrations, we used as many data points as

- 5 possible. We therefore compiled all available data from the literature and reported studies. Most of the data before the FNPP1 accident are included in the database "Historical Artificial Radionuclides in the Pacific Ocean and its Marginal Seas (HAM database)" (Aoyama and Hirose, 2004 and their updated version). The data recorded after the FNPP1 accident have been presented by Aoyama et al. (2016a). The term "surface seawater" as used in this study refers to a sample collected at a depth of less than 10 m.
- 10 We also focused on the Japanese government's monitoring data collected at Tomari (42.98-43.17°N, 140.21-140.30°E), Aomori (41.13–41.22°N, 141.50–141.67°E), Niigata (37.62–38.10°N, 138.38–138.84°E), Ishikawa (36.87–37.29°N, 136.43– 136.47°E), Fukui (35.75-36.09°N, 135.50-135.83°E), Shimane (35.67-35.80°N, 132.87-133.2°E), Saga (33.57-33.62°N, 129.73–129.98°E), and Kagoshima (31.58–31.93°N, 130.02–130.15°E) (Marine Ecology Research Institute, 2011, 2012, 2013, 2014, 2015, 2016) (Fig. 1). These measurements were taken once a year (from the middle of May to early June). Near the
- 15 Aomori sites, offshore monitoring was also conducted twice a year (May and October) at the Rokkasho Reprocessing Plant (39.5–41.4°N, 141.5–142.3°E). Seawater was sampled at various depths, from the surface to 664 m, at each monitoring site. Monitoring data (sites 304–01 [33.0°N, 127.7°E] and 105–11 [37.3°N, 131.3°E]) from the Korean government were also used in this analysis (Korea Institute of Nuclear Safety, 2011, 2012, 2013, 2014, 2015, 2016) (Fig. 1). At these monitoring sites, surface seawater (0 m depth) measurements were taken four times (February, April, August, and October) each year.
- 20

2.2 Measurement of ¹³⁴Cs activity concentrations

The ¹³⁴Cs activity concentrations in most of the monitoring datasets were below the limit of detection because of the low sensitivity of the measurement methods. We also collected seawater samples to investigate the spatial distribution of ¹³⁴Cs activity concentrations. The sample volumes ranged from a few litres to 10 L. The radiocaesium in the sampled seawater was

- extracted via the ammonium phosphomolybdate (AMP)/Cs compound method as improved by Aoyama and Hirose (2008b). 25 The ¹³⁴Cs and ¹³⁷Cs activity concentrations in the AMP/Cs compound were determined with the ultra-low-background gammaray detectors in the Low Level Radioactivity Concentration Laboratory of Kanazawa University (Hamajima and Komura, 2004). Aoyama and Hirose (2008b) and Aoyama et al. (2016a) have described the measurement procedure in detail. All radioactivity concentrations shown in this research were decay-corrected to the time of sample collection. In addition, we also determined ¹³⁴Cs/¹³⁷Cs activity ratios decay-corrected to 11 March 2011, the time of the FNPP1 accident. 30

2.3 Estimation of FNPP1-derived ¹³⁷Cs activity concentrations

In this study, we estimated the increase of ¹³⁷Cs activity concentrations due to the FNPP1 accident. The ¹³⁷Cs activity concentrations in the SOJ decreased exponentially after 1965. The decrease of the ¹³⁷Cs activity concentrations was become

to be slow from 2000 to 2010 (Fig. 2). By assuming that the apparent half-residence time of global fallout-derived ¹³⁷Cs was 35 approximately the same before and after the FNPP1 by using the negative exponential fitted curve, we estimated the global fallout-derived ¹³⁷Cs activity concentrations after the accident (Fig. SI1). The FNPP1-derived ¹³⁷Cs was then estimated from the difference between the measured activity concentrations and the values extrapolated from the exponential fitted curve during the period 2000-2010 (Fig. SI1).

2.4 Estimation of amounts of ¹³⁷Cs transported during 2012–2016

We estimated the amounts of FNPP1-derived ¹³⁷Cs transported in each region during 2012–2016 with Eq. (1):

Transport amount =
$$\sum_{i=2012}^{n}$$
 (FNPP1-derived ¹³⁷Cs activity concentration in year *i*) ×
(annual average seawater transport volume in year *i*), (1)

5

10

where n = 2016. We used the annual average FNPP1–derived ¹³⁷Cs activity concentrations at stations Saga and 304-11 for the ECS, station Shimane for the eastern TWC, and station 105-01 for the western TWC. We used station Aomori to estimate the amount of FNPP1-derived ¹³⁷Cs transported to the North Pacific Ocean via the Tsugaru Strait. The amount of FNPP1-derived ¹³⁷Cs transported northwards along the western coast of Hokkaido was estimated from the difference between the total inflow of FNPP1-derived ¹³⁷Cs at the entrance of the Tsugaru Strait its outflow from the strait. The annual average volume of seawater transported through the TWC was estimated from the data of Fukudome et al. (2010) and Han et al. (2016). The average volumes of TWC transported into the SOJ annually ranged from 2.59 ± 0.50 × 10⁶ m³ s⁻¹ to 2.82 ± 0.58 × 10⁶ m³ s⁻¹, of which

the average volumes of seawater transported through the east and west channels of the Tsushima Strait annually were 1.08 \pm 0.26–1.26 \pm 0.27 \times 10⁶ m³ s⁻¹ and 1.43 \pm 0.38–1.56 \pm 0.47 \times 10⁶ m³ s⁻¹ during 2012–2016, respectively. Nishida et al.

15 (2003) estimated the volume transported through the Tsugaru Strait to be $1.0-1.3 \times 10^6$ m³ s⁻¹; we used this value because we did not have *in situ* monitoring data for this value. The evaluation of seasonal variations was difficult in this study because the monitoring data were limited; relevant fluxes were measured once a year at the Japanese monitoring site and four times a year at the Korean monitoring sites.

20 3 Results

3.1 Increased ¹³⁷Cs activity concentrations in the ECS and the SOJ

Figure 2 shows the temporal variation in the ¹³⁷Cs activity concentrations in the surface seawater of the SOJ after the 1960s as well as the half-year average values. The ¹³⁷Cs activity concentrations decreased exponentially from 1960 to 1970; these concentrations originated from atmospheric nuclear weapons testing (Aoyama, 2010). The increase in the ¹³⁷Cs activity concentrations in 1986 was the result of the Chernobyl accident (Miyao et al., 1998). The apparent half-residence time during the period 1970–1990 was estimated to be 16.3 ± 0.5 years (Inomata et al., 2009). In the 2000s, the magnitude of the rate of decrease of ¹³⁷Cs activity concentrations was small, and the half-year average ¹³⁷Cs activity concentrations in the surface seawater reached a low of 1.5–2.4 Bq m⁻³. Within several months after the FNPP1 accident, high activity concentrations of ¹³⁷Cs, up to 3.3 Bq m⁻³, were observed. The ¹³⁷Cs activity concentrations were higher in the north-eastern part of the SOJ than
30 in the south-western part of the SOJ (Fig. 1). These high ¹³⁷Cs activity concentrations were associated with wet deposition of ¹³⁷Cs released into the atmosphere during the FNPP1 accident in March–April 2011. In addition to the abrupt increase of the ¹³⁷Cs activity concentrations just after the FNPP1 accident in 2011, the ¹³⁷Cs activity concentrations subsequently increased

- gradually in the SOJ (Aoyama et al., 2017). The ¹³⁷Cs activity concentrations in 2016 reached 2.6 Bq m⁻³, which was the same as the concentrations in 1998.
- 35 Figure 3 shows the FNPP1-derived ¹³⁷Cs activity concentrations measured at monitoring stations in the ECS and SOJ by the Japanese and Korean governments. These monitoring stations are located along a branch of the Kuroshio in the ECS and along the western and eastern TWC in the SOJ. The long-term variations in the ¹³⁷Cs activity concentrations and FNPP1derived ¹³⁷Cs at each monitoring station are also shown in Fig. SI2-9. With the exception of the high activity concentrations at Aomori in 2011 caused by the wet deposition of FNPP1-derived ¹³⁷Cs released to the atmosphere, an increase in the FNPP1-
- 40 derived ¹³⁷Cs in the SOJ started in 2012 and 2013. The FNPP1-derived ¹³⁷Cs gradually increased up to 1.3 Bq m⁻³ in 2016

(Fig. 3a, b). The lower activity concentrations at Niigata (Fig. 3b) were because the measurements were made at a station near Sado Island, off Niigata, rather than at the usual government monitoring site. At these monitoring stations, there was no significant trend of decreasing FNPP1-derived ¹³⁷Cs activity concentrations in 2015 and 2016. In contrast, the FNPP1-derived ¹³⁷Cs activity concentrations at station 314-01)

- 5 increased beginning in 2012–2013. The increase was clearly apparent after 2014 in the ECS. The FNPP1-derived ¹³⁷Cs activity concentrations were slightly lower in 2016 than in 2015. At station 105-11, which was located off South Korea (Fig. 1), marked increases in FNPP1-derived ¹³⁷Cs activity concentrations were observed in 2014, and FNPP1-derived ¹³⁷Cs activity concentrations reached approximately 1.4 Bq m⁻³ in 2015 (Fig. 3d). The FNPP1-derived ¹³⁷Cs concentrations were lower in 2016 than in preceding years.
- 10

The ${}^{134}Cs/{}^{137}Cs$ activity ratios in 2016 ranged from 0.27 to 0.51 (Fig. 4). There was no significant difference in the ${}^{134}Cs/{}^{137}Cs$ activity ratios among the stations in the ECS and the SOJ.

Figure 5 shows the temporal variations of the ¹³⁷Cs activity concentrations at different depths at station 314-01 in the ECS (Fig. 5a; 0–140 m) and at station 105-11 in the SOJ (Fig. 5b; 0–2000 m). Increases in the ¹³⁷Cs activity concentrations in the subsurface layer (at 140 m and 200 m at stations 314-01 and 105-11, respectively) occurred in 2013, approximately one year

- earlier than in the shallower layers. At station 314-01, the ¹³⁷Cs activity concentrations at a depth of 140 m were higher than those at the surface beginning in 2013. They increased up to 3.2 ± 0.28 Bq m⁻³ in 2014 and then tended to decrease after 2015. At shallower depths (0–50 m), ¹³⁷Cs activity concentrations increased in 2014 and did not significantly decrease in 2015 and 2016. At station 105-11, the increase of the ¹³⁷Cs activity concentrations started earlier in the subsurface seawater (200 m depth) in 2013. In 2014, the ¹³⁷Cs activity concentrations in surface seawater also increased and reached 2.8 ± 0.2 Bq m⁻³ in
- 20 2015. Decreases in the ¹³⁷Cs activity concentrations at 200 m and at the surface were observed after 2015, and a subsurface peak in the ¹³⁷Cs activity concentration at 200 m was not observed after 2015. Similar variations characterized by an increase of the ¹³⁷Cs activity concentration that started from the ocean interior were observed at the Kagoshima and Saga monitoring stations (Fig. SI10).

25 3.2 Propagation of radiocaesium from the upstream region (NPSJ and ECS) to the downstream region (the SOJ)

Figure 6 shows the distributions of the ¹³⁷Cs activity concentrations versus depth and σ_{θ} in the North Pacific South of Japan (NPSJ), in the ECS, and at station 105-11. In the NPSJ, the ¹³⁷Cs activity concentrations reached subsurface maxima of 8.2–12.3 Bq m⁻³ at approximately 300-m depth in 2012–2013 (Fig. 6a). Those high ¹³⁷Cs activity concentrations were measured in the region bounded by 136–138°E and 26–30°N. After 2014, a subsurface peak in the ¹³⁷Cs activity concentration was not

- 30 observed. The location of these subsurface peaks in ¹³⁷Cs activity concentrations in the layer corresponding to a σ_{θ} of 25.2 kg m⁻³ (Fig. 6b) is consistent with previous findings of a ¹³⁷Cs activity maximum in STMW with a σ_{θ} of 25.0–25.6 kg m⁻³ (Kaeriyama et al., 2014; Kumamoto et al., 2014). In the ECS, the ¹³⁷Cs activity concentrations gradually increased beginning in 2012 and reached a maximum (2.9 ± 0.24 Bq m⁻³) in 2015. The concentrations decreased in 2016 (Fig. 6c). High ¹³⁷Cs activity concentrations (>2 Bq m⁻³) in the ECS were found in the layer corresponding to σ_{θ} values of 23.6–25.2 kg m⁻³ (Fig.
- 6d). In contrast, ¹³⁷Cs activity concentrations at station 105-11 in the western SOJ decreased with increasing depth until 500 m (Fig. 6e). The highest ¹³⁷Cs activity concentrations at station 105-11 were measured in 2014 and 2015; they decreased in 2016. The ¹³⁷Cs activity concentrations that exceeded 2 Bq m⁻³ at station 105-11, except in one sample measured in 2015, were found at σ_{θ} values of 25.8–27.1 kg m⁻³ (Fig. 6f).

Figure 7 shows Hovmöller diagrams of ¹³⁷Cs activity concentrations at σ_{θ} values of 25.2 ± 0.5 kg m⁻³ along the TWC in 40 the ECS and at coastal sites in the eastern SOJ. These σ_{θ} surfaces were selected to show the maximum ¹³⁷Cs activity concentrations in the ECS. Figure SI11 shows the vertical distributions of the ¹³⁷Cs activity concentrations with depth and σ_{θ} at each monitoring station. Note that in the SOJ, the vertical distributions of the ¹³⁷Cs activity concentrations below 250 m were almost constant, and a subsurface peak of ¹³⁷Cs was not found at the monitoring stations along the eastern TWC (Fig. SI11). The ¹³⁷Cs activity concentrations before the FNPP1 accident were approximately 1.5 Bq m⁻³. In the ECS, the ¹³⁷Cs activity concentrations gradually increased and attained maxima during 2014–2015 (Fig. 7). The ¹³⁷Cs activity concentrations in the ECS tended to decrease in 2016 in a layer with a σ_{θ} of 25.2 ± 0.5 kg m⁻³. In the south-western part of the SOJ (Shimane,

- 5 Fukui, Ishikawa, and Niigata), the ¹³⁷Cs activity concentrations gradually increased beginning in 2012 and reached a maximum of 2.5 Bq m⁻³ during 2015–2016; those trends were almost the same as the trends at the monitoring stations in the ECS. In the north-western SOJ (Aomori and Tomari), the ¹³⁷Cs activity concentrations increased slightly and exceeded 2 Bq m⁻³ in 2016. These results indicate that the propagation of FNPP1-derived ¹³⁷Cs from the ECS (32–34°N) to the SOJ (35–38°N) along the TWC (Fig. 7) occurred within one year.
- 10

15

3.3 Transport process and total amount of FNPP1-derived ¹³⁷Cs transported into the SOJ during 2012–2016

Here we describe the possible pathway of FNPP1-derived ¹³⁷Cs from the Pacific Ocean to the SOJ via the ECS. The westwardflowing undercurrent would have transported FNPP1-derived ¹³⁷Cs in the STMW south-westwards, as reported by Oka (2009). The ¹³⁷Cs entrained in the STMW would have reached the western boundary of the SOJ at lower latitudes, and become entrained into the Kuroshio (Oka and Qiu, 2012) before being transported northwards to the west of Kyushu by the TWC bifurcation from the Kuroshio. The FNPP1-derived ¹³⁷Cs would then have entered the SOJ through the Tsushima Strait via the TWC. FNPP1-derived ¹³⁷Cs transported by the TWC would have been divided into western (coastal stations in Korea) and eastern (eastern coast of the Japanese Islands) portions. The remaining FNPP1-derived ¹³⁷Cs in the eastern TWC would have

been transported northwards along the western coast of Hokkaido (Fig. 8). The integrated FNPP1-derived ¹³⁷Cs in the ECS

- during 2012–2016 was estimated to be 0.21 ± 0.01 PBq, which corresponds to 5.0 % of the FNPP1-derived ¹³⁷Cs in the STMW (4.2 ± 1.1 PBq) estimated by Kaeriyama et al. (2016) (Table 1). The bifurcation of the TWC resulted in transport of 0.11 ± 0.01 PBq of FNPP1-derived ¹³⁷Cs in the eastern channel, which corresponds to 2.6 % of the FNPP1-derived ¹³⁷Cs in the STMW. The amount of FNPP1-derived ¹³⁷Cs transported in the western channel was estimated to be 0.09 ± 0.01 PBq, which corresponds to 2.1 % of the FNPP1-derived ¹³⁷Cs injected into the STMW. The amounts of FNPP1-derived ¹³⁷Cs in the eastern
- and western outflows are consistent with the range of uncertainty for the inflow amounts, 0.21 ± 0.01 PBq. A small part of the transported FNPP1-derived ¹³⁷Cs (0.09 ± 0.01 PBq; 2.1 % of FNPP1-derived ¹³⁷Cs in STMW) was returned to the North Pacific Ocean via transport through the Tsugaru Strait. In other words, the amount of FNPP1-derived ¹³⁷Cs that was returned to the North Pacific Ocean corresponded to 43 % of the total amount of FNPP1-derived ¹³⁷Cs transported to the SOJ and 2.1 % of the estimated total amount of FNPP1-derived ¹³⁷Cs in the STMW. The remaining 0.03 ± 0.002 PBq (14 % of the transported
- 30 FNPP1-derived ¹³⁷Cs in the SOJ; 0.7 % of the transported FNPP1-derived ¹³⁷Cs in STMW) would have been transported to the northern part of the SOJ (west of Hokkaido) or, in part, to the interior of the ocean via deep convection and surface mixing.

4 Discussion

4.1 Signature of FNPP1-derived ¹³⁷Cs inflow in the SOJ by using ¹³⁴Cs/¹³⁷Cs activity ratio

- 35 According to atmospheric model simulations, atmospheric deposition of FNPP1-derived ¹³⁷Cs occurred over a wide region in the western North Pacific Ocean (30–55°N, 140°E–180°) (e.g., Aoyama et al., 2016b). One of the regions where ¹³⁷Cs was deposited south of the Kuroshio and Kuroshio Extension corresponded to the region of STMW formation (Aoyama et al., 2016b; Oka et al., 2012). The release of FNPP1-derived radiocaesium into the atmosphere occurred at the end of March and early April 2011. Because the deposition of FNPP1-derived ¹³⁷Cs into the North Pacific Ocean was therefore a point source
- 40 with respect to time, FNPP1-derived radiocaesium is a very useful tracer for investigating transport of FNPP1-derived

radiocaesium in the North Pacific Ocean. The vertical distributions of the ¹³⁷Cs activity concentrations in the NPSJ indicated that FNPP1-derived ¹³⁷Cs was entrained in STMW (Fig. 6).

There were several indicators of the transport process: (i) maximum ¹³⁷Cs activity concentrations were observed in the subsurface layer rather than the surface seawater, (ii) σ_{θ} data indicated that the ¹³⁷Cs activity concentrations were highest in

- 5 STMW, (iii) in the ECS, the similarity of the σ_{θ} of ¹³⁷Cs-contaminated seawater to the σ_{θ} of STMW is an indication that FNPP1-derived ¹³⁷Cs was transported into the ECS via STMW from the NPSJ, and (iv) the ¹³⁷Cs activity concentrations in the northern ECS (>30°N) were higher than those in the southern ECS (<30°N) (Fig. SI12). In this study, however, there were not enough data to elucidate the transport route in more detail.
- Figure 9 shows the latitudinal distribution of the ¹³⁴Cs/¹³⁷Cs activity ratio, which was decay-corrected to 11 March 2011.
 The ¹³⁴Cs/¹³⁷Cs activity ratio ranged from 0.1 to 0.72, and the ratios in the Ogasawara region and in the ECS were almost the same as those in the SOJ (Fig. 9a). Considering that the ¹³⁴Cs/¹³⁷Cs activity ratio in the radiocaesium that originated from the FNPP1 accident was almost 1 (Busseler et al., 2011), variations in the ratio indicated that seawater contaminated with FNPP1-derived radiocaesium had mixed with seawater contaminated with global fallout–derived radiocaesium during transport. The highest activity concentration ratio (0.72), which was found near Kagoshima, is an indication of the highest contribution of
- 15 FNPP1-derived radiocaesium. In contrast, the relatively low 134 Cs/ 137 Cs activity ratio in the region bounded by 30–32°N implies a small contribution of FNPP1-derived radiocaesium to that region of the Pacific Ocean. Within the ECS, the 137 Cs activity concentrations tended to increase northwards as suggested by Aoyama et al. (2017) (Fig. SI12). The 137 Cs activity concentrations measured at Okinawa in the southern ECS (http://search.kankyo-hoshano.go.jp/servlet/search.top?pageSID=113836570) averaged approximately 1.7 ± 0.47 Bq m⁻³, slightly higher than those
- 20 measured before the FNPP1 accident (Fig. SI13). The implication is that less FNPP1-derived radiocaesium was transported to the southern ECS than to the northern ECS, as shown in Fig, SI12.

4.2 Advection and vertical mixing of FNPP1-derived ¹³⁷Cs in the SOJ

In this study, we revealed that FNPP1-derived ¹³⁷Cs entered the SOJ via the ECS. FNPP1-derived ¹³⁷Cs was then transported northward with the TWC. In the SOJ, there was a time lag of approximately one year in the propagation of FNPP1-derived radiocaesium (Fig. 7). Based on measurements of phosphate, one of the dominant seawater nutrients, Kodama et al. (2016) have revealed that the phosphate concentrations in surface seawater of the SOJ during winter are positively correlated (p < 0.05) with the phosphate concentrations in the saline ECS seawater during the preceding summer, and the surface water of the southern SOJ is almost entirely replaced by ECS seawater during May–October. They have also suggested that the transport of water-soluble constituents from the ECS to the SOJ takes at least ~0.5 years. The propagation of FNPP1-derived radiocaesium into the SOJ is consistent with the timescale of propagation of changes of nutrient concentrations from the ECS

to the SOJ (Kodama et al., 2016).

The ¹³⁷Cs activity concentrations at station 105-11, located along the western side of the TWC in the SOJ, were

- highest at the surface and gradually decreased with increasing depth (Fig. 6e). This vertical distribution differed from those in 35 the NPSJ (Fig. 6a) and ECS (Fig. 6c). In particular, the subsurface peak observed in the NPSJ and ECS did not appear at station 105-11. At station 105-11, most of the ¹³⁷Cs was in seawater with a σ_{θ} of 25.7–27.3 kg m⁻³ (Fig. 6f), higher than the σ_{θ} in the NPSJ and ECS. A similar vertical distribution was also observed along the western coast of the Japanese Islands on the eastern side of the TWC (Fig. SI11). These distributions were due to cooling of the surface layer after water was transported through the Tsushima Strait. Physical processes such as the convergence and subduction of surface water inside eddies are important
- 40 mechanisms of downward transport of radiocaesium (Miyao et al., 1998; Budyansky et al., 2015). There is a possibility that the downward transport of radiocaesium is seasonal. The ¹³⁷Cs derived from global fallout should have already penetrated below the surface layer and have accumulated in the deeper layers of the SOJ.

4.3 Mass balance of FNPP1-derived ¹³⁷Cs in the SOJ

The most reliable estimates of the amount of FNPP1-derived ¹³⁷Cs deposited in the North Pacific Ocean via atmospheric release and direct release to the Ocean are 11.7–14.8 PBq (Aoyama et al., 2016b; Tsubono et al., 2016) and 3.5 ± 0.7 PBq

- 5 (Tsumune et al., 2012, 2013), respectively. The FNPP1–derived ¹³⁷Cs inventory in the North Pacific Ocean has been estimated to be 15.2–18.3 PBq by comparing the observed inventory with model simulation results (Aoyama et al., 2016b), 15.3 ± 2.6 PBq by optimum interpolation analysis (Inomata et al., 2016), and 16.1 ± 1.4 PBq by model simulation (Tsubono et al., 2016). According to the estimation by Kaeriyama et al. (2014), the amount of ¹³⁴Cs in the STMW was approximately 4.2 ± 1.1 PBq in 2012. The estimation by Kaeriyama et al. (2014) implies that the FNPP1-derived ¹³⁷Cs transported into the SOJ from 2012
- 10 to 2016 accounted for 5.0 % of the FNPP1-derived ¹³⁷Cs inventory in the STMW. Approximately 60–65 % of the total inflow of FNPP1-derived ¹³⁷Cs in the SOJ was transported in 2015 and 2016. After entering the SOJ, the FNPP1-derived ¹³⁷Cs followed different paths. The amounts of FNPP1-derived ¹³⁷Cs transported along the eastern TWC (2.6 % of the FNPP1-derived ¹³⁷Cs inventory in the STMW) and western TWC (2.1 % of the FNPP1-derived ¹³⁷Cs inventory in the STMW) were similar or slightly larger along the former path. Of the FNPP1-derived ¹³⁷Cs transported in the SOJ, approximately 43 %
- 15 returned to the North Pacific Ocean through the Tsugaru Strait during 2012–2016.

Because 5 % of the FNPP1-derived ¹³⁷Cs in the STMW was transported into the SOJ, 95 % may remain in the STMW. On the basis of long-term measurements of the ¹³⁷Cs activity concentration adjacent to the FNPP1, Tsumune et al. (2017) have estimated that the rate of direct release of FNPP1–derived ¹³⁷Cs was 2.2×10^{14} Bq day⁻¹ until November 2011, after which it decreased exponentially with time to 3.9×10^9 Bq day⁻¹ on 26 October 2015. Assuming that the rate of decrease of the ¹³⁷Cs

- 20 activity concentrations remained the same from 26 October 2015 to 31 December 2016, the total amount of ¹³⁷Cs directly released from the FNPP1 site during the period 2012–2016 has been estimated to be 0.03 PBq (Tsumune et al., 2017). However, not all of the directly released ¹³⁷Cs was subducted into the STMW. An amount equal to 0.03 PBq corresponds to 0.7 % of ¹³⁷Cs inventory in the STMW. We can conclude that the FNPP1-derived ¹³⁷Cs in STMW was decreasing during the study period.
- An analysis of historical data from 1950 to 2000 indicates that the ¹³⁷Cs activity concentrations in the western North Pacific Ocean were decreasing exponentially during that time. However, the ¹³⁷Cs activity concentrations during 2000–2010 were almost constant at 1.5–2 Bq m⁻³ (Inomata et al., 2009). Considering that there was scarcely any global fallout–derived ¹³⁷Cs deposition after the 1970s, the ¹³⁷Cs activity concentrations in the seawater of the North Pacific Ocean were controlled by physical oceanographic processes such as advection and diffusion from roughly 1980 until the FNPP1 accident (Inomata et al.,
- 30 2009). Several studies have reported that there were subsurface maxima of ¹³⁷Cs derived from global fallout in layers corresponding to surfaces of constant σ_{θ} in the STMW and CMW (e.g., Aoyama et al., 2008a). A possible explanation for the constancy of ¹³⁷Cs activity concentrations during 2000–2010 is that the ¹³⁷Cs subducted into the STMW and CMW in the 1960s might have returned to the surface after a few decades. However, the increase of FNPP1-derived ¹³⁷Cs activity concentrations in the SOJ began in 2012–2013. This increase implies the existence of a faster transport route from the North
- 35 Pacific Ocean to the SOJ via the subtropical gyre.

5. Conclusion

The ¹³⁷Cs activity concentrations in the Sea of Japan (SOJ) increased beginning in 2012–2013 and reached a maximum in 2015–2016 of approximately 3 Bq m⁻³, which is above the pre-Fukushima accident level of 1.5 Bq m⁻³. The ¹³⁴Cs/¹³⁷Cs activity

40 ratios of 0.36–0.51 in the ECS and the SOJ are evidence that the increase in the ¹³⁷Cs activity concentration was derived from the Fukushima accident.

An increase of FNPP1-derived ¹³⁷Cs activity concentrations was first observed in the subsurface layer with a σ_{θ} of ~25.2 kg m⁻³ (corresponding to STMW) in the southern part of the Kuroshio Current in the NPSJ in 2012–2013. The ¹³⁷Cs activity concentrations in the NPSJ have been decreasing since 2014. In the ECS, an increase of FNPP1-derived ¹³⁷Cs was observed in 2014; decreases have been observed since 2016. Vertical distributions of the ¹³⁷Cs activity concentrations in the ECS were

- 5 almost constant or contained a subsurface peak. These results indicated that there was a 1–2 year time lag between the maxima of ¹³⁷Cs activity concentrations in the NPSJ and ECS. The increase of the ¹³⁷Cs activity concentrations in the SOJ began in 2012 and continued until 2016. A time lag in the propagation of FNPP1-derived ¹³⁷Cs of approximately one year was observed in the SOJ. The similarity of ¹³⁴Cs/¹³⁷Cs activity ratios in the surface layers of the ECS, SOJ, and Ogasawara region suggest that the source of radiocaesium was the same in all three of these regions.
- 10 The total amount of recirculated FNPP1-derived ¹³⁷Cs from 2012 to 2016 was estimated to be 0.21 ± 0.01 PBq, which corresponds to 5.0 % of the FNPP1-derived ¹³⁷Cs in the STMW. Of this total, the amounts of FNPP1-derived ¹³⁷Cs transported along the western and eastern TWC were almost the same or slightly larger along the latter. Of the FNPP1-derived ¹³⁷Cs transported into the SOJ, approximately 43 % (2.1 % of the total amount in STMW) passed through the Tsugaru Strait and back into the North Pacific Ocean. The FNPP1-derived ¹³⁷Cs transported northwards was estimated to be 14 % of the amount in STMW).
 - The most important result of this study was the determination that FNPP1-derived ¹³⁷Cs was rapidly transported into the SOJ within several years after the FNPP1 accident.

Figure 1: Location of the sampling points after the FNPP1 accident. Large black circles are sites monitored by the Japanese government. Blue circles are sites monitored by the Korean government. Black triangles are sites with measured vertical profiles. Circle colors corresponds to the ¹³⁷Cs activity concentrations measured in 2011. Open circles are sites measured after

30 profiles. Circle colors corresponds to the ¹³⁷Cs activity concentrations measured in 2011. Open circles are sites measured after the FNPP1-accident. The area around Japan was divided into 3 regions: the SOJ, ECS, and NPSJ (<141.5°E). The locations of monitoring stations are also plotted in the upper Figure.

Figure 2: Temporal variations in the ¹³⁷Cs activity concentrations in surface seawater in the Sea of Japan during the period
 from1960 to 2016. Circles indicate measured values, and red circles indicate data measured after the accident (2011 March 11). Black circles indicate the 0.5-year average value. Standard deviations of data were removed to clearly show the temporal variation.

Figure 3: Temporal variations in the FNPP1–derived ¹³⁷Cs activity in the surface seawater at the monitoring sites in Japan after 2011. FNPP1–derived ¹³⁷Cs: (a) Tomari, Aomori, (b) Niigata, Ishikawa, Fukui, Shimane, (c) Saga, Kagoshima, 314-01, and (d) 105-11.

Figure 4: Temporal variations in the ¹³⁴Cs/¹³⁷Cs activity concentration ratio in the surface seawater at the monitoring stations in Japan from Jan 2016 to Jun 2016. (a) Tomari, Aomori, (b) Niigata, Ishikawa, Fukui, Shimane, and (c) Saga, Kagoshima.

Figure 5: Temporal variations in the ¹³⁷Cs activity concentrations at stations (a) 314-01 and (b) 105-11.

45 Figure 6: Vertical distributions of the ¹³⁷Cs activity concentrations over the (a) depth profile in the NPSJ, (b) potential density anomaly profile in the NPSJ, (c) depth profile in the ECS, (d) potential density profile in the ECS, (e) depth profile at 105-01

along the WTWC, and (f) potential density anomaly profile at 105-01 along the western TWC. Colour indicates the collection time (year).

Figure 7: Hovmoller diagrams of the ¹³⁷Cs activity concentrations at a potential density anomaly along with an eastern TWC
 at a potential density anomaly of 25.2 ±0.5 kg m⁻³. The ECS stations described on the x-axis are Kagoshima and Saga stations. Southwestern SOJ includes the monitoring stations Shimane, Fukui, Ishikawa, and Niigata. The northwestern SOJ includes the monitoring stations cloor indicates the ¹³⁷Cs activity concentrations (Bq m⁻³).

Figure 8: Schematic diagram of the FNPP1-derived ¹³⁷Cs transport in the North Pacific Ocean. The bold line indicates the Kuroshio pathway. The thin lines indicate the flow pathway of the Tsushima Warm Current. The circle with red dotted line are STMW formation area. The dotted green circle indicates the CMW formation area. Unfilled blue arrows indicate the FNPP1-derived ¹³⁷Cs transport route deduced in this study. The red circles indicate the entrance region in the ECS. The estimated accumulated flux during the period from 2012 to 2016 at each section is shown in the parenthesis. The inventory in the STMW (*) was deduced by Kaeriyama et al. (2016).

Figure 9: Latitudinal and horizontal distributions of the ¹³⁴Cs/¹³⁷Cs activity ratios measured at the coastal sites of the SOJ and ECS in 2015-2016. The values were radioactive decay corrected to 11th March, 2011. The data measured in the Ogasawara area (red circles in (b)) were also added. (a) latitudinal distribution, (b) horizontal distribution.

Figure 1: Location of the sampling points after the FNPP1 accident. Large black circles are sites monitored by the Japanese government. Blue circles are sites monitored by the Korean government. Black triangles are sites with measured vertical profiles. Circle colours correspond to the ¹³⁷Cs activity concentrations measured in 2011. Open circles are sites measured after
 the FNPP1 accident. The area around Japan was divided into 3 regions: the SOJ, ECS, and NPSJ (<141.5°E). The locations of monitoring stations are also plotted in the upper Figure.

Figure 2: Temporal variations in the ¹³⁷Cs activity concentrations in surface seawater in the Sea of Japan during the period from 1960 to 2016. Circles indicate measured values, and red circles indicate data measured after the accident (2011 March 11). Black circles indicate the 0.5-year average value. Standard deviations of data were removed to clearly show the temporal variation.

Figure 3: Temporal variations in the FNPP1–derived ¹³⁷Cs activity concentrations in the surface seawater at the monitoring stations in the SOJ after 2011. (a) Tomari, Aomori, (b) Niigata, Ishikawa, Fukui, Shimane, (c) Saga, Kagoshima, 314-01, and (d) 105-11.

Figure 4: Temporal variations in the ¹³⁴Cs/¹³⁷Cs activity concentration ratio in the surface seawater at the monitoring sites in Japan from Jan 2016 to Jun 2016: (a) Tomari, Aomori, (b) Niigata, Ishikawa, Fukui, Shimane, and (c) Saga, Kagoshima.

Figure 5: Temporal variations in the ¹³⁷Cs activity concentrations at sites (a) 314-01 and (b) 105-11.

Figure 6: Vertical distributions of the ¹³⁷Cs activity concentrations over the (a) depth profile in the NPSJ, (b) potential density anomaly (σ_{θ}) profile in the NPSJ, (c) depth profile in the ECS, (d) σ_{θ} profile in the ECS, (e) depth profile at 105-01 along the WTWC, and (f) σ_{θ} profile at 105-01 along the western TWC. Colour indicates the collection time (year). Horizontal red line shown in (b) and (d) means the boundary value of σ_{θ} of the STMW.

Figure 7: Hovmoller diagram of the ¹³⁷Cs activity concentrations at a potential density along with an eastern TWC at a potential density of 25.2 \pm 0.5 kg m⁻³. The ECS stations described on the x-axis are Kagoshima and Saga stations. Southwestern SOJ includes the monitoring stations Shimane, Fukui, Ishikawa, and Niigata. The northeastern SOJ includes the monitoring stations Aomori and Tomari. Color indicates the ¹³⁷Cs activity concentrations (Bq m⁻³). Arrow indicate the propagation of FNPP1-¹³⁷Cs transport from ECS to SOJ.

Figure 8: Schematic diagram of the FNPP1-derived ¹³⁷Cs transport in the North Pacific Ocean. The bold line indicates the Kuroshio pathway. The thin black lines indicate the flow pathway of the Tsushima Warm Current. The pink region is STMW formation area. The green region is the L-CMW formation area, and the blue region indicates the TRMW and D-CMW formation area. The estimated accumulated flux during the period from 2012 to 2016 at each section is shown. The inventory in the STMW was deduced by Kaeriyama et al. (2016).

Figure 9: Latitudinal and horizontal distributions of the ¹³⁴Cs/¹³⁷Cs activity ratios measured at the coastal sites of the SOJ and ECS in 2015-2016. The values were radioactive decay corrected to 11th March 2011. The data measured in the Ogasawara area (red circles in (a)) were also added. (a) Latitudinal distribution, (b) horizontal distribution.

Current.				
Flow	Station	Transport amount (PBq)*	Ratio against to STMW(%)	Ratio against to inflow into the SOJ (%)
		Inflow to SOJ		
ECS to SOJ	Saga/304-01	0.21 \pm 0.01	5.0 ± 2.3	
		At Tsushima Strait		
Western TWC	105-11	0.09 ± 0.01	2.1 ± 1.2	43 ± 10
Eastern TWC	Shimane	0.11 ± 0.01	2.6 ± 1.4	50 ± 7
		Two branches of eastern TWC		
Outflow to Pacific Oceans	Aomori off	0.09 ± 0.01	2.1 ± 1.2	43 ± 10
Northward Transport	Tomari	0.03 \pm 0.002	0.7 ± 0.3	14 ± 2

Table 1. Estimated transport amount of FNPP1–derived ¹³⁷Cs in the monitoring site in the SOJ along with the Tsushima Warm Current.

5 *The value was decay corrected to 11th March 2011. ECS were estimated by using the average value of 314-01 and Saga monitoring sites. The transport amount (*) were estimated by sum of the duration from 2012 to 2016.
