Abstract

A multiyear, ocean glider dataset, obtained along a representative cross-shelf transect along the Rottnest continental shelf, south-west Australia, was used to characterise the seasonal and inter-annual variability of water column properties (temperature, salinity, and chlorophyll fluorescence distribution). All three variables showed distinct seasonal and inter-annual variations that were related to local and basic scale ocean atmosphere processes. Controlling influences for the variability were attributed to forcing from two spatial scales: (a) local scale (due to Leeuwin Current and dense shelf water cascades, DSWC); and, (2) basin scale (El Niño Southern Oscillation, ENSO events). In spring and summer, inner shelf waters were well mixed due to strong wind mixing and deeper waters (>50m) were vertically stratified in temperature that contributed to the presence of a subsurface chlorophyll maximum (SCM). On the inner shelf, chlorophyll fluorescence concentrations were highest in autumn and winter. DSWCs were also the main physical feature during autumn and winter. Chlorophyll fluorescence concentration was higher closer to the sea bed than at the surface in spring, summer, and autumn. The seasonal patterns coincided with changes in the wind field (weaker winds in autumn) and air–sea fluxes (winter cooling and summer evaporation). Inter-annual variation was associated with ENSO events. Lower temperatures, higher salinity, and higher chlorophyll fluorescence (>1mgm⁻³) were associated with the El Niño event in 2010. During the strong La Niña event in 2011, temperatures increased and salinity and chlorophyll fluorescence decreased (<1mgm⁻³). It is concluded that the observed seasonal and inter-annual variability in chlorophyll fluorescence concentrations were related to the changes in physical forcing (wind forcing, Leeuwin Current and air-sea heat and moisture fluxes).
1. Introduction

Almost all life forms rely on primary production, directly or indirectly, to survive, and phytoplankton in the ocean perform most of the primary production (Field et al., 1998). Among the phytoplankton pigment, chlorophyll $a$ (denoted as chlorophyll in the following description), is an important biological indicator of phytoplankton biomass in the water column. Environmental variables, such as light availability (Sverdrup, 1955; Huisman and Weissing, 1994), water temperature (Eppley, 1992; Hambright et al., 1994; Paerl and Huisman, 2008), and salinity (Karsten et al., 1995), affect phytoplankton biomass variability. Seasonal cycles of phytoplankton concentrations are identifiable signals of the annual growth activity in pelagic systems (Cebrían and Valiela, 1999; Winder and Cloern, 2010). In many parts of the world, a spring bloom—an increase in phytoplankton concentrations in response to seasonal changes in temperature and solar radiation—is common and usually present for a few weeks to months (Cushing, 1959; Sommer et al., 1986; Pattiaratchi et al., 1989). Often a secondary peak in production develops in late summer or autumn (Longhurst, 1995). These seasonal phytoplankton patterns have large inter-annual variability across different geographic regions (Cebrían and Valiela, 1999; Cloern and Jassby, 2008; García-Soto and Pingree, 2009). Satellite and field-based measurements have shown that in the oligotrophic waters off south-west Australia, the seasonal chlorophyll cycle (a proxy for phytoplankton biomass) is different from that in other regions, with a clear peak in chlorophyll concentrations in late autumn or early winter and minimal levels in spring and summer (Koslow et al., 2008; Thompson et al., 2011; Lourey et al., 2012). Pearce et al. (2006) found higher chlorophyll concentrations on the continental shelf than further offshore. In this paper, we present an extensive, multiyear, ocean glider dataset, obtained along a representative cross-shelf transect along the Rottnest continental shelf (RCS), south-west Australia, to explore the seasonal and inter-annual variability of water column properties (temperature, salinity, and chlorophyll fluorescence distribution). Although ocean gliders have been sampling the oceans for more than a decade, sustained observations addressing the variability at the seasonal and inter-annual scales from continental shelf regions are almost non-existent and this study addresses this shortcoming.

Changes in phytoplankton biomass at seasonal and inter-annual timescales are important components of the total variability associated with biological and biogeochemical ocean processes (Ghisolfi et al., 2015). The circulation along the Western Australian coast has been studied through observations and the use of ocean models (Gerbach et al., 1999; Feng et al., 2003; Twomey et al., 2007; Woo and Pattiaratchi, 2008; Wijeratne et al., 2018); however, methods to study the biological processes in the water column have been limited to the use of satellite ocean colour data (Moore et al., 2007; Lourey et al., 2017) and limited shipborne observations (Hanson et al., 2005a; Pearce et al., 2006; Koslow et al., 2008). Satellite imagery is limited to processes at the sea surface as sensors are unable to image subsurface waters due to limitations in light penetration. Information on the role of physical forcing and the biological responses in the water column has been limited because of the absence of a comprehensive observational dataset. In south-west Australia, majority of the available oceanographic and biological data are restricted in time and space and are thus unsuitable to be used to study seasonal and inter-annual patterns.

Eastern boundaries of ocean basins are typically associated with upwelling of higher nutrient water into the euphotic zone leading to high primary productivity on the continental shelf and rich coastal fisheries (Codispoti,
Oceanographic conditions off RCS are dominated by the Leeuwin Current (LC) that suppress upwelling and transports nutrient poor water along the continental shelf and has a negative impact on primary productivity (Koslow et al., 2008; Twomey et al., 2007). The absence of upwelling and major river systems means that the region is low in nutrients. For example, Twomey et al. (2007) reported dissolved nitrate concentrations on continental shelf and in the surface 50m further offshore were typically below detection levels (<0.016 µM). Nitrate concentrations increased rapidly beyond 150 m depth to concentrations of around 30 µM. Thus the RCS is a nutrient poor environment with nutrient supply limited to that through recycling during storms and offshore supply through eddy activity (Koslow et al., 2008).

The Rottnest continental shelf (RCS) has several distinct bathymetric features (Figure 1a): (1) a shallow inshore region (depths < 10 m), which can be defined as a ‘leaky’ coastal lagoon with a line of discontinuous submerged limestone reefs; (2) an upper continental shelf terrace, with a gradual slope and a mean depth of ~40 m, located from ~10–40 km from the coast; (3) an initial shelf break at the 50 m isobath; (4) a lower continental shelf between the 50 and 100-100 m isobaths, where the depth increases sharply; and, (4) the main shelf break at the 200 m isobath. The major current systems in the region are the Leeuwin and Capes currents (Woo and Pattiaratchi, 2008; Wijeratne et al., 2018). The Leeuwin current (LC) is a warm, lower salinity, poleward-flowing, eastern boundary current, which mainly flows along the 200 m isobath (Ridgway and Condie, 2004; Pattiaratchi and Woo, 2009). In this oligotrophic environment lower chlorophyll and nutrient concentrations (Hanson et al., 2005a; Twomey et al., 2007) and lower primary productivity (Hanson et al., 2005b; Koslow et al., 2008) characterise the LC. The LC, which is strongest in autumn and winter, transport ~5-6 Sv of water during austral winter and ~2 Sv during austral summer poleward (Feng et al., 2003; Wijeratne et al., 2018). El Niño and La Niña cycles influence the Leeuwin current: the current is weaker during El Niño events and stronger during La Niña events (Pattiaratchi and Buchanan, 1991; Wijeratne et al., 2018). Of interest to this study, the region experienced a marine heat wave in February and March 2011, which was associated with the warming related to the La Niña event defined as Ningaloo Niña (Feng et al., 2013). This event increased the Leeuwin current’s volume transport in February—an unusual event at this time of the year—and resulted in unprecedented warm sea surface temperature anomalies (~5 °C higher than normal) off Australia’s west coast (Feng et al., 2013).

The Capes current, which is dominant in summer, is a wind-driven, inner shelf current, generally formed in water depths < 50 m (Gersbach et al., 1999). It transports cooler, upwelling-derived water northward past Rottnest Island (Figure 1) between October and March (Pearce and Pattiaratchi, 1999; Gersbach et al., 1999).

Continental shelf processes along the Rottnest continental shelf are mainly wind driven, given the low diurnal tidal range (~0.6 m) (Pattiaratchi and Elliot, 2008). The seasonal wind regime in the region can be divided into three regimes (Verspecht and Pattiaratchi, 2010; Pattiaratchi et al., 2011): (1) spring and summer (September–February)—strong, daily sea breezes dominate, with southerly winds often exceeding 15 m/s; (2) autumn (March–May)—the transition from the summer to the winter regimes occurs, and wind speeds are usually low; and (3) winter (June–August)—storms occur frequently. Storm systems are associated with the passage of frontal systems with the region subject to peak wind speeds to 30 m/s. These winds are generally north-westerly in winter.
and southerly in summer (Verspecht and Pattiaratchi, 2010). In the study region winter storms have a typical pattern with strong north/north-easterly components blowing for 12 to 52 hours, followed by a period of similar duration when storms turn south/south-westerly, with no prevailing direction dominating for the duration of the storm. Summer storms are southerly over a period of 3–4 days that are enhanced by the sea breeze system in the afternoon. Calm wind conditions are mainly observed during autumn and winter (March–August; between winter storm fronts) and are characterized by low wind speeds (<5 m/s).

Another major feature of the dynamics is the presence of dense shelf water cascade (DSWC) on the continental shelf (Pattiaratchi et al., 2011). Western Australia experiences high evaporation rates resulting in higher salinity (density) water in the majority of shallow coastal waters. This dense water is transported across the continental shelf close to the seafloor due to the density difference between the nearshore and offshore water (Pattiaratchi et al., 2011; Mahjabin et al., 2019). It is a major mechanism for the export of water containing suspended material and chlorophyll away from the coastal zone. Analysis of ocean glider measurements by Pattiaratchi et al. (2011) indicated that DSWC is a regular occurrence along the RCS particularly during autumn and winter months. In autumn the dense water formation is mainly through changes in salinity resulting from evaporation whilst in winter, temperature was dominant through surface cooling. In summer, although there is a cross-shelf density (due to salinity) gradient, DSWC is not present due to wind induced vertical mixing.

The use of ocean gliders as an observational tool has several advantages over traditional, ship-based surveys. Ocean gliders have high sampling frequencies and long sampling durations (Pattiaratchi et al., 2017); the high temporal and spatial resolution data obtained with gliders may provide a better understanding of the links between the physical (meteorological and oceanographic) forcing and the phytoplankton response; all the relevant data are collected simultaneously and are not weather limited. We used a multiyear (2009–2015) ocean glider dataset (50 individual missions) along a repeated transect to examine the variability in the physical parameters and chlorophyll fluorescence concentration (a measure of phytoplankton biomass) distribution over seasonal and interannual timescales. The seven-year timescale included two El Niño events (2010 and 2014) and a strong, extended La Niña event (2011–2013). The aims of this paper, through the analysis of the long-term ocean glider dataset, were to: (1) examine the seasonal and inter-annual variability in chlorophyll fluorescence along the Rottnest continental shelf; (2) relate the seasonal chlorophyll fluorescence variability to changes in temperature and salinity distribution and local wind forcing; and, (3) determine the influence of the ENSO cycles on chlorophyll fluorescence. This is the first long term study of seasonal processes in the continental shelf waters along the RCS.

This enables the identification of the main mechanisms that drive the variations in phytoplankton, as represented by chlorophyll fluorescence along the RCS.

This paper is organised as follows: Section 2 describes the methods. The results of the seasonal winds and the monthly, seasonal, and inter-annual variations in the chlorophyll and physical properties are described in Section 3. In Section 4, we discuss the possible causes of the observed variability. A general conclusion is then given in Section 5.

5
2. Methods

Water column data were obtained from repeated surveys undertaken using Teledyne Webb Research Slocum electric gliders (http://www.webbresearch.com/) along the Two Rocks transect off Rottnest continental shelf, south-west Australia (Figure 1). The Slocum ocean glider is 1.8 m long, 0.213 m in diameter and weighs 52 kg. It is designed to operate in coastal waters of up to 200 m deep where high manoeuvrability is required under relatively strong background currents. Ocean gliders are autonomous underwater vehicles that propel themselves through the water by changing their buoyancy relative to the surrounding water (Rudnick, 2016). By alternately reducing and expanding their volume, ocean gliders can descend and ascend through the ocean water column using minimal energy. In contrast to other similar automated ocean sampling equipment (e.g. Argo floats; http://www.argo.ucsd.edu/), ocean gliders have wings, a rudder and a movable internal battery pack allowing them to move horizontally in a selected direction in a saw tooth pattern. This allows for the horizontal position to be controlled and to sample particular regions of the ocean. The gliders are remotely controlled via the Iridium satellite system and navigate through waypoints, fixing their position via the Global Positioning System (GPS). Each time the glider surfaces, the data and new waypoints can be relayed via satellite to and from the glider. The autonomous nature of the ocean gliders means that they are able to collect data continuously irrespective of the weather conditions.

The data set were collected over a seven year (2009–2015) period. Gliders are operated by the Integrated Marine Observing System (IMOS) Ocean Glider facility located at The University of Western Australia (Pattiaratchi et al., 2017). All the ocean glider data are available through the Australian Ocean Data Network (https://portal.aodn.org.au). More than 200 cross shelf transects from ~50 ocean glider missions were analysed, with ~28 million individual scans obtained for each variable (temperature, salinity and chlorophyll).

Each cross shelf ocean glider transect took two to three days to complete (Pattiaratchi et al., 2011), with the gliders travelling at a mean speed of 25 km/day. The glider transects extended from ~20 m depth contour to deeper waters (the gliders have a maximum depth range of 200 m) and collected data from the surface to ~2 m above the sea bed. The gliders were equipped with a Sea-Bird Scientific pumped CTD (conductivity–temperature–depth) sensor, a WETLabs BBFLSLO 3 parameter optical sensor (which measured chlorophyll fluorescence, coloured dissolved organic matter, and backscatter at 660 nm), and an Aanderaa oxygen optode. All the sensors sampled at 4 Hz (which yielded measurements about every 7 cm in the vertical). The actual vehicle trajectory was transposed onto the Two Rocks transect as a straight line (Pattiaratchi et al., 2011).

IMOS data streams are provided in NetCDF-4 format with ocean glider data files containing meta-data and scientific data for each glider mission. Subsequent to the ocean glider recovery, all the data collected by the glider are subject to Quality Assurance and Quality Control (QA/QC) procedures that include a series of automated and manual tests (Woo, 2017). To maintain data integrity all of the sensors (CTD and optical sensors) are returned to the manufacturers for calibration after a period 365 days in the water. The Sea-Bird Scientific SBE 41CP pumped CTD sensor on the Slocum gliders is the same as those mounted on Argo floats and achieve temperature and salinity accuracies of ±0.002°C and ±0.01 salinity units, respectively.
The WETLabs BBFL2SLO 3 fluorescence values were estimated using the conversions provided by the manufacturer. A recent study by Beck (2016) found that, through inter-comparison between chlorophyll a derived from HPLC and Wetlabs BBFL2SLO 3 derived fluorescence on ocean gliders, the original manufacturer’s recommendation for the estimation of chlorophyll a from fluorescence provided the best estimate. As part of the QA/QC procedures applied to the WETLabs BBFL2SLO 3 Eco Puck sensor on the Slocum gliders are subject to a series tests to track their performance, to identify errors and to quantify drift during missions due to biofouling and/or damage. These tests were undertaken in the laboratory prior to shipping of the glider, immediately prior to deployment on the vessel, and then immediately on recovery before cleaning of the sensor face. The tests were carried out by attaching a solid standard in a holder a set distance from the sensor face and collecting engineering counts from the fluorescence, CDOM and backscatter signals over a 5 minute period. The solid standards used for fluorescence and CDOM counts, Plexiglas Satinice® plum 4H01 DC (polymethylmethacrylate, Evonik Industries), was identified by Earp et al. (2011) in a review of fluorescent standards for calibration of optical instruments as being the optimum. The ocean glider deployments started in 2008 and performance of ECO Puck sensors has been documented over this period. This included comparing consecutive scale factors following factory calibrations. Our records demonstrated the inherent stability of these sensors in their fluorescent and backscatter measurements, with the difference between fluorescence scale factors between calibrations over 8 years of service typically < 6%. To measure the reliability of the instruments between factory calibrations, the fluorescent response of the instruments to a fluorescein concentration curve have been tracked between factory calibrations. We have also undertaken field measurements (Thomson et al., 2015) where a glider was attached to a rosette sampler and collected concurrent data from the glider and Niskin bottles at surface, mid-depth and bottom of the water column in 100m depth. Water samples were subjected to HPLC analyses to determine the ‘true’ Chlorophyll a concentrations. The comparison between Wetlabs BBFL2SLO 3 derived fluorescence and the HPLC chlorophyll a concentrations was very good with a correlation squared ($r^2$) value of 0.75 (n > 100) in the range 0.17 to 0.21 mg m$^{-3}$.

Wind speed and direction, recorded at 30 min intervals, were obtained from the Bureau of Meteorology weather station at Rottnest Island, and located ~ 40 km south of Two Rocks transect (Figure 1a).

The focus of this paper is on the seasonal and inter-annual variability in the temperature, salinity, and chlorophyll fluorescence concentrations across the Two Rocks transect. It was assumed that processes along this transect were representative of the cross-shelf variability across the Rottnest continental shelf. When we refer to the ‘chlorophyll concentration’ (units mg m$^{-3}$), we are referring to the chlorophyll fluorescence as recorded by the BBFL2SLO optical sensor. Salinity is expressed as a dimensionless quantity.

When examining the seasonal changes it was found that the changes in the mean values obscured the seasonal variability of each parameter (temperature, salinity, and chlorophyll). Hence, in addition to presenting the measured values (see supplementary Figure S1) we also calculated anomalies to remove the influence of the seasonal variability. The procedure for each parameter (~28 million individual points) was as follows: (1) data were interpolated onto a common grid across the cross shelf transect; (2) transects were then sorted according to season: spring (September-November), summer (December-February), autumn (March-May) and winter (June-
August; (3) the mean value across the whole transect (i.e. through water depth and across distance) for each season was calculated (Table 1); and, (4) the anomaly at each grid point was calculated by subtracting the seasonal mean from values at each point.

3. Results

3.1 Seasonal winds

The mean winds for each season from March 2010 to March 2014 showed southerly winds were prevalent in summer, autumn, and spring, followed by south/south-easterly winds (Figure 2). Summer storms, which were usually associated with southerly winds, lasted up to 36 hours with speeds > 25 ms⁻¹. The sea breeze usually contributed to the southerly winds, which reinforced the prevailing southerly winds found in the seasonal rose plots (Figure 2). In autumn, the wind speeds decreased (< 13 ms⁻¹), whereas in winter, the winds had no prevailing direction. This is typical of winter storms, which are associated with rapid changes in the wind direction (Veraspecht and Pattiaratchi, 2010). In spring, the winds were southerly, with mean wind speeds of 15 ms⁻¹. The southerly winds in the study region are upwelling favourable.

The time series of the daily mean wind speeds and directions in 2010 revealed the changes that occurred in the wind regime: from November to May (the summer regime), the winds were generally southerly, and the mean wind speeds were ~7.5 ms⁻¹ in November and ~10 ms⁻¹ in January and February (Figure 3). The wind speeds decreased between March and mid-May (the autumn regime), with few changes in the wind direction. Between mid-May and October (the winter regime), winter storms caused large fluctuations in the wind speed and direction.

3.2 Seasonal temperature, salinity, and chlorophyll distribution

Typical cross-shore distributions of the seasonal variation in temperature, salinity, and chlorophyll along the Two Rocks transect during spring, summer, autumn, and winter are shown in Figure 4.

In spring (21–23 October 2013), the temperature and salinity in the upper 80 m were vertically mixed across the whole shelf. The temperature and salinity characteristics changed at the shelf break. On the upper continental shelf (< 40 m depth), the inshore water were cooler and less saline than the offshore waters (Figure 4a). High chlorophyll concentrations (up to 1.2 mg m⁻³) were found on the inner shelf and at the 50 m shelf break (Figure 4a), which corresponded to temperature and salinity gradients (i.e. frontal system) in the same region. A thin layer (< 10 m) of subsurface chlorophyll maximum (SCM) (up to 1 mg m⁻³) extended from the shelf break to offshore, and coincided with the halocline (and pycnocline) at about 80m depth.

In summer (28 February–3 March 2014), a plume of warm Leeuwin current water (~23.5°C) was located in the top ~30 m between 60 and 70 km offshore (Figure 4b). This plume cooled (to 23°C) and thinned in the top ~5 m as it moved inshore. Water on the upper continental shelf was cooler that offshore. The salinity on the upper continental shelf (~35.7) was slightly higher than offshore (35.5); the Capes current most likely caused the cooler and saltier inshore waters. The cooler and saltier water on the upper continental shelf revealed that higher density water was present on the shelf and a small, dense shelf water cascade (DSWC) was present inshore of the...
shelf break. A subsurface chlorophyll maximum (up to 1.2 mg m⁻²) was located from the shelf break to offshore.

In autumn (18–21 May 2009), the nearshore waters were saltier and cooler (21°C) than the offshore waters (22.5°C) (Figure 4c). The offshore waters were well mixed except in the bottom 20 m. A plume of salty (35.7) and cooler (21°C) water, which extended to ~60 km across the entire continental shelf and depths > 180 m, was observed inshore and indicated the presence of DSWC. The maximum chlorophyll concentration (1.3 mg m⁻²) was located on the upper continental shelf in the shallow pycnocline. The chlorophyll levels were generally higher in the DSWC than they were in the surface waters on the upper continental shelf. In the offshore waters, higher chlorophyll water was uniformly distributed in the surface mixed layer to depths of 60 m close to the shelf break and depths > 120 m farther offshore (Figure 4c).

In winter (9–11 August 2012), the temperature increased from 18°C inshore to 20.7°C offshore, and the water column was generally vertically mixed (Figure 4d), except between 10 and 20 km on the upper continental shelf. The salinity was uniformly distributed inshore and in most offshore regions. Maximum chlorophyll (> 1 mg m⁻²) concentrations were found along the inner shelf between 10 and 20 km and corresponded to the region of vertical and horizontal temperature and salinity gradients.

The ocean glider data indicated vertical and horizontal stratification across the shelf and the temperature and salinity distribution across the shelf changed seasonally. The temperature and salinity characteristics on the upper continental shelf were often different from those farther offshore. High chlorophyll concentrations were found in regions with strong temperature and salinity gradients and thus density. These maximum values occurred in the vertical (e.g. the SCM in summer and autumn) and the horizontal (e.g. at the shelf break in spring and winter).

3.3 Monthly mean temperature, salinity, and chlorophyll concentrations

The monthly mean temperature and salinity for inshore and offshore waters (upper 40 m depth) were calculated, except during July, September, November, and December because only a single ocean glider transect was available in each of these months. Inshore waters were defined as region where depth < 40m, and offshore waters were defined as region where depth > 40m. The temperature and salinity structure indicated that from January to March (summer to early autumn), the inshore waters (< 40 m depth) increased (~21.1–23.0°C) and the salinity decreased (35.81 to 35.77) (Figure 5a). From March to August (autumn to winter), the temperature (23.0 to 19.0°C) and salinity both decreased (35.77 to 35.22). From August to January (winter to early summer), both temperature (18.9 to 21.1°C) and salinity increased (35.22 to 35.8). Offshore water (> 40 m depth) showed a similar seasonal pattern to that of the inshore waters (Figure 5b). Except that from January to March, the salinity decrease in offshore waters (from 35.71 to 35.54) was larger compared to inshore waters and from August to January, the offshore water temperature dropped slightly before increasing to 21.0°C.

Spatially averaged chlorophyll concentrations for the inshore waters revealed significant seasonal variability (Figure 5a). Higher chlorophyll concentration values were reached between March and August (autumn to winter), with a maximum of 1.12 mg m⁻² reached in May and decreased to a minimum of 0.36 mg m⁻² in February. The
chlorophyll concentration values for offshore waters were less variable with highest values in May (maximum of 0.85 mg m$^{-3}$) and lowest in February (minimum of 0.43 mg m$^{-3}$, Figure 5b). Higher chlorophyll concentrations corresponded with warmer and less saline water for both the inshore and offshore waters.

3.4 Seasonal distribution

Over the seven-year study period (January 2009–March 2015), the vertical structure of the seasonal mean data for the Rottnest continental shelf revealed variability in the temperature, salinity, and chlorophyll concentrations. Anomalies are defined as departures from the seasonal average, with positive (negative) values higher (lower) than the seasonal average. The anomalies allowed us to examine the relative changes in water properties across the whole transect for each season.

Temperature anomaly

Seasonal temperature anomaly in the continental shelf waters differed from those further offshore, seaward of the shelf break (Figure 6). During spring, the temperature distribution indicated that water to be vertically well mixed on the upper continental shelf (Figures 6a, S1a) and vertically stratified in depths >40 m. The offshore water in the upper layer was warmer compared to those on the inner shelf. In summer, the warmer surface water extended across the entire continental shelf (Figure 6b). Water along the middle of the shelf (5–20 km from the coast) was slightly cooler, most likely due to the influence of the Capes Current. In autumn and winter, the upper shelf waters were cooler than the offshore waters. The temperature anomalies were mostly negative, with the lowest values (~1°C) attained close to the coast (between 0 and 7 km) (Figures 6c–d).

The largest variability in the offshore waters was associated with the thermocline depth (temperature anomaly of about ~1.0°C). In spring, the thermocline was almost horizontal and located at ~120 m depth. In summer, the thermocline was located higher in the water column (~70 m depth), with a slight inclination (deeper in the offshore). In autumn, the thermocline depth increased to 100 m, with a more pronounced inclination. The thermocline inclination in summer and autumn was most likely due to upwelling processes when the winds were upwelling-favourable (Figure 2). In winter, the thermocline was absent because the Leeuwin current dominated the offshore waters.

Salinity anomaly

In summer and autumn, the salinity anomaly was higher on the upper shelf than in the offshore waters, mainly because of evaporation (Figures 7b, c). A cross-shelf salinity gradient was also present. The salinity was more uniform in the surface waters offshore. In spring, high salinity water was present at >100 m corresponding to the colder water (Figure 7a). In winter, salinity gradients were absent along the whole transect (Figure 7d).

Chlorophyll concentration anomaly

The chlorophyll concentration anomalies revealed there were seasonal variations in the upper shelf and offshore waters (Figure 8). Across the whole transect, high chlorophyll concentration anomalies were present in the subsurface waters (i.e. not at the surface) and along the upper shelf. In spring, the highest chlorophyll concentration anomaly was found at the shelf break (Figure 8a) and was related to a horizontal temperature gradient (Figure 6a). A subsurface chlorophyll maximum (SCM) at ~100 m depth was present in the offshore
waters aligned with the vertical stratification in temperature and salinity and depth (Figures 6a, 7a, 8a). In summer, the SCM was concentrated over a smaller depth range (<50 m) in the offshore waters. On the continental slope, seaward of the shelf break (an area of 20–30 km), the chlorophyll concentration anomalies were more diffuse, most likely because of the variation in the upwelling and the diurnal cycle (Chen et al., 2017). In autumn and winter, the SCM was absent, but the chlorophyll concentration anomalies were higher on the upper continental shelf. The autumn chlorophyll distribution corresponded to the presence of DSWCs on the upper shelf (Figures 7c and 8c).

### 3.5 Depth-integrated mean variability

We used a seven-year dataset of ocean glider deployments to examine the interannual variability in the temperature, salinity, and chlorophyll concentration. Water properties were depth averaged from the surface to 30 m depth (Figure 9). The gliders traverse in a sawtooth pattern, and as the depth increases, the surfacing spacing increases; thus there were gaps in the data for the deeper waters. All the water properties showed seasonal changes, but in this section, we focus on the interannual variability. For example, the marine heat wave during the 2011 La Niña events is evident (red lines - summer 2011) as well as the cooler summers in 2009 and 2015 (yellow lines). Similarly, higher salinities were recorded during summers 2010, 2014, 2015 that were associated with El Niño events (red lines).

The year-to-year summer temperature range was >4°C; the temperature was <20.1°C in February 2010 and increased to a maximum of 24.4°C in March 2011 and also in February 2012 (Figure 9a). This maximum temperature was associated with the persistent La Niña event in 2011-2012. In winter, the year-to-year temperature range was >3°C; the temperature was >21.2°C in 2011 and decreased to a minimum of 18.4°C in 2012 and 2014.

The concurrent depth-averaged salinity time series showed the waters were less saline (34.9) in August 2011 than they were in other years (Figure 9b). In March 2015, the highest salinity value (~35.9) was measured on the upper shelf. The lowest value (~35.5) was attained in 2011 and was associated with the warmer water.

The depth-averaged chlorophyll concentrations also had strong interannual variation (Figure 9c), with values ranging from 0.81 mg m⁻³ in May 2009 and 2010 to 1.8 mg m⁻³ in May 2014. The largest range in the chlorophyll concentrations was from March 2011 (chlorophyll concentration of 0.88 mg m⁻³) to March 2014 (chlorophyll concentration of 0.14 mg m⁻³). The lowest value of 0.18 mg m⁻³ was also recorded in March 2013.

Time series of the depth-averaged (surface 30 m) temperature, salinity, and chlorophyll measured 10 km from the coastline revealed strong seasonal and interannual variability, especially in response to El Niño and La Niña events (Figure 10). Information presented in Figure 10 includes the same as that shown in Figure 9, except that variations at a single point (10 km) are shown as a time series. The seasonal cycle (Section 3.3; Figure 5a) indicated warmer, saltier water was present in summer and cooler, less saline water in winter.

In 2009/10, a moderate El Niño event occurred, which resulted in lower temperatures and higher salinity during the first half of 2010. The El Niño weakened the Leeuwin current, which entrained cooler, saltier water into the
3.6 Temperature, salinity, and chlorophyll during a storm event

The ocean glider data obtained from 17 to 28 April 2013 revealed a storm caused vertical mixing in the water column and transported higher chlorophyll water from the SCM to the surface. The first two transects (17–20 April 2013) were collected under low wind (< 5 m s⁻¹) conditions (Figure 11). The water column was vertically stratified across the whole transect with the DSWC present on the upper shelf (Figures 12a,b). Higher chlorophyll water was present in the DSWC’s bottom layer. In the deeper waters, the higher chlorophyll water was associated with the SCM (Figures 12m, n).

On 20 April, the winds increased to > 10 m s⁻¹. The winds were initially southerly and then changed to westerly and continued to be that way to 23 April (Figure 11) causing vertical mixing of the water column. By 25 April, the water column on the upper shelf was vertically mixed (Figures 12c, k). On 28 April, when the winds decreased, the water column on the upper shelf was vertically stratified in salinity (Figure 12l).

The winds and the vertical stratification also affected the chlorophyll distribution. Initially, high chlorophyll concentrations were found in the DSWC on the upper shelf close to the seabed and in the SCM in the offshore waters (Figure 12m). As the winds increased, the chlorophyll concentration became uniform through the water column across the whole transect (Figure 12q). Note that the wind, although not strong (< 10 m s⁻¹), was able to mix the water column to ~80 m depth in the offshore waters and erode the thermocline and thus the SCM. The SCM likely reformed (Figure 12s); however, with reduced solar heating and convective cooling, the stratification would have weakened, which would have led to a well-mixed water column in late autumn and early winter.
4. Discussion

In this paper, simultaneous water column data of ocean properties (temperature, salinity and chlorophyll fluorescence) together with meteorological data were used to examine the seasonal and inter-annual variability along the Rottnest continental shelf. Acquisition of multi-year sustained ocean observations using shipborne sampling is difficult (relative high cost and weather dependence) and thus many studies have used satellite remote sensing data of sea surface temperature and ocean colour to determine seasonal and inter-annual variability on continental shelves (e.g. Nieto and Melin, 2017; Kilpatrick et al., 2018). Here, ocean glider data collected along a single transect along the RCS shelf over the period 2009-2015 indicated distinct seasonal and interannual variation in temperature, salinity and chlorophyll concentrations.

The study region is located at 32°S, close to the critical latitude (30°S), where the inertial period is 24 hours. Because the diurnal sea breeze system also has a ~24 hour period, resonance occurs, which generates near-inertial waves (Mihanović et al., 2016; Chen, 2018). Field measurements revealed that near-inertial waves force the thermocline to oscillate at a diurnal timescale, with a vertical excursion > 50 m (Mihanović et al., 2016; Chen, 2018). This vertical excursion of the thermocline causes the thermocline to migrate along the continental slope on a diurnal timescale. This process has a strong influence on the sub-surface chlorophyll maximum (SCM) interaction at the continental slope: the chlorophyll anomaly indicates higher concentrations along the slope between water depths 50 m (shelf break) and 120 m (Figure 8b).

The study region is located in a Mediterranean climate zone, with hot, dry summers and mild, wet winters. The annual evaporation rate exceeds 2 m (Pattiaratchi et al., 2011). There are no major land-based freshwater inputs to the region. Although the Swan River discharges at Fremantle, its freshwater component is low because rainfall is low during summer and autumn, and the river discharge is mainly deflected south in winter (Pattiaratchi et al., 2011). The combination of evaporation and cooling is such that in summer, coastal heating and evaporation result in a band of warm, high salinity water close to the coast; in winter, the nearshore waters are cooler through mixing with offshore water (Pattiaratchi et al., 2011).

The impacts of all the physical forcing at the seasonal scale were reflected in the temperature and salinity (T/S) distribution across the shelf. The T/S structure across the continental shelf showed the water was warmest on the upper shelf between January and March whilst the salinity increased from January to March (Figure 5). The warming was due to high solar insolation and the higher salinity through evaporation. From March to August, both the temperature and salinity decreased. This temperature decrease was due to heat loss to the atmosphere despite the transport of warmer water into the region by the Leeuwin Current. The salinity decrease was due to the advection of lower salinity water from the Leeuwin current. From August to January, both the temperature and salinity increased because of the increasing solar insolation and evaporation. The offshore waters showed a similar seasonal pattern.

In general, both inshore and offshore chlorophyll concentrations were higher in autumn and winter (March to August) than they were in spring and summer. Maximum values were attained in May for the inshore (1.1 mg·m⁻³) and offshore waters (0.85 mg·m⁻³). The chlorophyll difference between summer and winter inshore (0.75 mg·m⁻³)
was larger than it was offshore (0.45 mg m⁻²). A similar seasonal pattern was found in studies conducted over the past two decades. Pearce et al. (2000) found offshore chlorophyll concentrations between 1979 and 1986 were highest between May and August. Fearns et al. (2007) found a clear seasonal cycle, with maximum values attained between May and July from 1997 to 2004.

The main differences between spring/summer and autumn/winter were found in the water column structure, especially in the offshore regions. The offshore waters were vertically stratified in spring and summer and vertically mixed in autumn and winter (Figures 6–8). The pycnocline in spring and summer initiated the SCM. Koslow et al. (2008) observed the summer SCM in a layer above the nutricline at 100 m depth when the water column was stratified. The nearshore autumn bloom coincided with the DSWCs, which regularly occur in autumn (Pattiaratchi et al., 2011). In winter, high chlorophyll concentrations were uniformly distributed inshore because of winter cooling and storm-induced mixing of the water column (Longhurst, 2007; Koslow et al., 2008; Chen et al., 2017).

Our results are in broad agreement with those of Koslow et al. (2008), who used ship-based sampling data and satellite remote sensing data to study phytoplankton in the same region. Koslow et al. (2008) found that: (1) the primary productivity and chlorophyll concentrations were lower offshore in summer when the water column was stratified and most of the chlorophyll was contained in the SCM; (2) phytoplankton blooms in late autumn and winter coincided with the period when the Leeuwin current flow was strongest, and the winter bloom was due to cooling and storms, which promoted mixing of the upper water column. We also observed higher autumn and winter chlorophyll concentrations and a vertically mixed upper water column in the offshore region. In addition, the surface chlorophyll features agreed with Kämpf and Kavi (2017), who show widespread phytoplankton blooms (chlorophyll concentrations ~1 mg m⁻²) during autumn and winter using satellites data along the southern Australia coastline.

One of the unique features of the study region is that it does not follow well established processes and seasonality like in other regions globally. Although the study region is located in an eastern ocean basin – it is not a major upwelling region (similar to off Peru/Chile or South Africa). This is mainly because of the presence of the Leeuwin Current which flows southwards against the prevailing upwelling favourable winds that promotes downwelling (Pattiaratchi and Woo, 2008). Rossi et al. (2013) applied a composite dynamical upwelling index that accounted for the role of alongshore pressure gradients counteracting the coastal Ekman divergence. The results indicated that upwelling was sporadic along the whole WA coast with the occurrence of transient upwelling events lasting 3–10 days changing in space and time. The study region (at 31.5°S) consisted of up to 12 upwelling days per month during the austral spring/summer. The intensity of intermittent upwelling was influenced by the upwelling favourable winds, the characteristics of the Leeuwin Current and the local topography. Thus the system is very different to other eastern boundaries. Also, maximum chlorophyll values presented here are factor 10 lower than those observed off South Africa. In addition to this, maximum chlorophyll levels were observed during late autumn/early winter and thus not during the period upwelling favourable southerly winds are present. In summer the most persistent feature was the sub-surface chlorophyll maximum when strong upwelling favourable winds occurred. Autumn was characterised by low wind speeds and winter does not contain any persistence in the
prevailing winds (see Figure 2 and 3). Although other upwelling regions such as off Peru and South Africa does respond to ENSO events- mainly due to changes in the wind field, here the response is mainly due to changes in the strength of the Leeuwin Current that determined changes in the chlorophyll concentrations rather than upwelling.

An indication of the role of the Leeuwin Current (LC) and the wind regime influencing the chlorophyll concentrations are highlighted in the autumn peaks in 2009 and 2014. The LC is strongest in autumn and winter (mean transport: ~5–6 Sv) and weaker during summer (mean transport: ~2 Sv). Wijeratne et al. (2018) presented results of boundary current transport around Australia from a high resolution simulation over a 15 year period. The transport across a cross-shelf section at 31.5°S extending to the deeper ocean indicated that in January/February of 2009 and 2014 the southward mean monthly transport of the LC was very weak (< 0.5 Sv). In contrast, during the period 2010-2013 the monthly mean transport over these months was > 1.0 Sv. Here, the weaker LC leads to a shallower mixed layer during the summer. Thus, when the storms arrive in late autumn the shallow mixed layer is broken down more easily bringing nutrients onto the upper layer that allows for higher phytoplankton growth and thus higher chlorophyll. The vertical mixing by storms were highlighted in Figure 12.

Also the number of major storms that impacted the study region over the period April-June were as follows: 2009: 7; 2010: 2; 2011: 5; 2012: 0; 2013: 5; 2014: 7. i.e. the period 2009 and 2014 had more storms compared to other years. The autumn chlorophyll concentrations 2009 and 2014 were related to a weaker LC and the incidence of increased number of storms.

In summary, the observed patterns of seasonal variability in the chlorophyll concentrations were related to the changes in the water’s physical properties, which were affected by the seasonally changing physical forcing. These findings were similar to those from Vidal et al.’s (2017) study of the Iberian continental shelf, which is a region with similar dynamics (e.g. eastern poleward boundary current, upwelling-favourable winds) to the Rottnest continental shelf. Vidal et al. (2017) found that the physical forcing’s frequency and intensity affected the chlorophyll variability.

In spring and summer, the offshore waters were vertically stratified, with a surface mixed layer and a well-defined pycnocline; the Leeuwin current was weak and located farther offshore (Pearce and Pattiaratchi, 1999). The strong, sustained winds mixed the upper water column to > 50 m depth. The pycnocline prevented nutrients moving from beneath the pycnocline; however, the high light penetrating into this region allowed the SCM to form. At the shelf break, the pycnocline moving along the slope and on the upper shelf caused higher chlorophyll concentrations at the shelf break and in the bottom layer. In spring, the higher chlorophyll concentrations at the shelf break were located where there were temperature gradients between the upper shelf and the offshore waters (i.e. a shelf break thermal front was present; Figures 6 and 8).

4.1 Interannual variability

The ocean glider dataset collected between 2009 and 2015 revealed strong interannual variability in the region (Figure 10). Pearce and Feng (2013) analysed large-scale (monthly), satellite-derived, sea surface temperature data and found that coastal water temperatures off south-west Australia varied interannually and were linked to
the ENSO cycle. During La Niña events, a strong Leeuwin current transported warm water southwards (Pattiaratchi and Buchan, 1988; Pearce and Philips, 1988; Feng et al., 2003, 2008), whereas during El Niño events, the Leeuwin current was weaker with generally lower water temperatures (Pattiaratchi and Buchan, 1988; Pearce et al., 2006). Several ENSO events occurred during the study period (http://www.bom.gov.au/climate/enso/Inlist/): (1) the 2009–2010 El Niño; (2) the 2010–2013 La Niña; and (3) 2014–2015 neutral conditions.

The study region experienced a ‘marine heat wave’ in February and March 2011, which was related to a La Niña event and defined as Ningaloo Niña (Feng et al., 2013). This event increased the Leeuwin current’s volume transport in February and caused high sea surface temperature anomalies (~5 °C higher than normal) (Feng et al., 2006). The glider data revealed that extreme depth-integrated (upper 30 m) temperatures (up to 3.5 °C above average) occurred in March 2011 and February 2012 (Figure 9).

The glider data captured the transition between the 2009–2010 El Niño and the extended 2011–2014 La Niña (Figure 10). Large changes in the temperature (increase > 4°C) and salinity (decrease by 0.5) occurred between the El Niño and the La Niña events. The temperature decreased and the salinity increased over the same period, with an accompanying decrease in the chlorophyll concentration from ~1 mg m⁻³ in 2011 to < 0.25 mg m⁻³ in early 2014. A strong Leeuwin current, which transported warmer, low salinity, low nutrient water from the north to the south, affected the interannual variability in the temperature and salinity and most likely the chlorophyll concentration. A small decrease in the number of winter storms between 2011 and 2014 (Wandres et al., 2017) might also have reduced local recycling of nutrients (Chen et al., 2017).

The extended impacts of the heat wave have significant ecological impact, causing temperate reef communities in Western Australia (Wernberg et al., 2016). The decrease in the chlorophyll concentrations between 2011 and 2014 showed the heat wave affected the pelagic and benthic ecosystems over an extended period. Wernberg et al. (2016) reported that the heat wave effects persisted for many years, and almost five years after the heat wave, the kelp forests had not recovered.
5. Conclusions

A seven-year, high-resolution ocean glider dataset indicated that the temperature, salinity, and chlorophyll a distribution along the Rottnest continental shelf exhibited strong seasonal and interannual variability. Based on the results of the data analysis the following conclusions were reached:

- The seasonal variability was controlled by changes in the physical forcing that included winds, formation of dense shelf water cascades and strength of the Leeuwin Current. The chlorophyll concentrations were higher during autumn and winter across the whole transect.

  **Inner continental shelf (< 50 m):**
  - During spring and summer months, the water column was vertically well mixed due to strong wind mixing. In autumn and winter, DSWCs were the main physical feature.
  - Chlorophyll concentrations were higher closer to the sea bed than at the surface during spring, summer, and autumn. In winter the chlorophyll concentrations were uniform through the water column.

  **Outer continental shelf (> 50 m):**
  - During spring and summer months the water column was vertically stratified in temperature that contributed to the formation of a subsurface chlorophyll maximum (SCM).
  - With the onset of storms in autumn, the water column was well mixed with the SCM absent.

- Inter-annual variation was associated with ENSO events. Lower temperatures, higher salinity, and higher chlorophyll concentrations were associated with the El Niño event in 2010. During the strong La Niña event in 2011, temperatures increased and salinity and chlorophyll concentrations decreased. Over subsequent years, the temperatures gradually decreased, the salinity increased, and the chlorophyll concentrations continued to decrease. In autumn of 2014, the chlorophyll concentrations increased.

Acknowledgments and data

The ocean glider data used in this paper were collected as part of the Integrated Marine Observing System (IMOS) by the Ocean Glider located at the University of Western Australia. IMOS is a national collaborative research infrastructure program, supported by the Australian Government through the National Collaborative Research Infrastructure Strategy (NCRIS). The meteorological data were obtained from the Bureau of Meteorology. Funding for this study was provided by International Postgraduate Research Scholarship, Australian Postgraduate Award and University Postgraduate Award to MC. The authors acknowledge the support of Dennis Stanley, Paul Thompson, Kah Kiat Hong, and Mun Woo in the tasks associated with the deployment, recovery, piloting, and data QA/QC of the ocean gliders. All the ocean glider data are available through the Australian Ocean Data Network (https://portal.aodn.org.au).
