# 28 Abstract

29	The Three Gorges Dam (TGD), located in the mainstream of the Yangtze River, is the
30	world's largest hydroelectric station in terms of installed power capacity. It was
31	demonstrated that the TGD had caused considerable modifications in the downstream
32	freshwater discharge due to its seasonal operation mode of multiple utilisation for flood
33	control, irrigation, and power generation. To understand the impacts of the freshwater
34	regulation of TGD, an analytical model is adopted to explore how the operation of TGD
35	may affect the spatial-temporal patterns of tide-river dynamics in the Yangtze River
36	estuary. We evaluated the effect of TGD by comparing the changes in major tide-river
37	dynamics in the post-TGD period (2003-2014) with those in the pre-TGD period
38	(1979–1984). The results indicate that the strongest impacts occurred during the autumn
39	and winter, corresponding to a substantial reduction in freshwater discharge during the
40	wet-to-dry transition period and slightly increased discharge during the dry season. The
41	underlying mechanism leading to changes in the tide-river dynamics lies in the
42	alteration of freshwater discharge, while the impact of geometric change is minimal.
43	Overall, the results suggest that the spatial-temporal patterns of tide-river dynamics is
44	sensible to the freshwater regulation of the TGD, to the extent that the ecosystem
45	function of the estuary may undergo profound disturbances. The results obtained from
46	this study can be used to set scientific guidelines for water resource management (e.g.
47	navigation, flood control, salt intrusion) in dam-controlled estuarine systems.

49 river dynamics, Yangtze River estuary

## 50 1. Introduction

51 Estuaries are transition zones where river meets ocean (Savenije, 2012). Tide-river interactions, a result of both hydrologic drivers and geomorphic constraints, are highly 52 dynamic in estuaries (Buschman et al., 2009; Sassi and Hoitink, 2013; Guo et al., 2015; 53 54 Cai et al., 2016; Hoitink and Jay, 2016; Hoitink et al., 2017). In natural conditions, they usually experience a wide range of temporal variations, including spring-neap tidal 55 56 fluctuations as well as seasonal-varying discharges (e.g. Zhang et al., 2018). Human 57 intervention, such as dam construction in the upstream parts of the river and the growing 58 number of water conservancy projects being built along large rivers (such as freshwater withdrawal), have caused seasonal changes in downstream freshwater discharge 59 delivery, leading to adjustments in the function of fluvial and estuarine hydrology (e.g. 60 61 Lu et al., 2011; Mei et al., 2015; Dai et al., 2017). Consequently, it is important to 62 understand the impacts of large-scale human intervention, which are relevant not only to tide-river dynamics and riparian ecology but also to sustainable water resource 63 management in general, such as flood control, navigation, salt intrusion, and freshwater 64 65 withdrawal.

66

River discharge generally fluctuates following a wet-dry cycle due to the seasonal variation of precipitation in the upstream river basin. For instance, the Yangtze River, a large river, which flows into the East China Sea, has a maximum river discharge during summer in July and a low value during winter in January, with a maximum discharge difference of approximately 38,000 m<sup>3</sup>/s (Cai et al., 2016). Similar seasonal variations

72	are also identified in other large rivers in eastern and southern Asia, such as the Mekong
73	River in Vietnam, Ganges River in India, and Pearl River in China, under the influence
74	of a monsoon climate. However, most large rivers have been significantly dammed at
75	the central and upper reaches in recent decades, dramatically modifying stream
76	hydrology and sediment delivery, resulting in changes in hydraulics and river delta
77	development trend at the lower reaches (e.g. Räsänen et al, 2017; Rahman et al., 2018;
78	Liu et al., 2018). Due to the fact that the response of tide-river interactions to the
79	impacts of dams are diverse and non-uniform and that many more dams are to be built
80	in the future, the impacts of the hydrodynamic interactions between tidal waves and
81	seasonal river flows from natural variations and anthropogenic activities have become
82	a common focus in international hydraulic research, especially in large tidal rivers.

83

The Yangtze River estuary, located near the coastal area of East China Sea, is one of the 84 largest estuaries in Asia. In the mouth of the Yangtze River estuary, bifurcation occurs 85 and the characteristics of tides have been broadly investigated in previous studies (e.g. 86 Zhang et al., 2012; Lu et al., 2015; Alebregtse and Swart, 2016). However, in these 87 studies, river influences are usually neglected. In recent years, the processes of 88 nonlinear interactions between tidal wave and river flow in the Yangtze River estuary 89 have received increasing attention (e.g. Guo et al., 2015; Zhang et al., 2015a, b; Cai et 90 al., 2016; Kuang et al., 2017; Zhang et al., 2018). However, recent studies that have 91 been mainly concerned with tidal properties, such as asymmetry, changes near the 92 mouth area, and seasonal variations in tidal wave propagation and fluvial effects over 93

the entire 600 km of the tidal river, up to the tidal limit of the Datong hydrological 94 95 station, have been limited. In addition, the operation of the Three Gorges Dam (TGD), the largest dam in the world, has substantially affected the downstream river hydrology 96 and sediment delivery. There is a variety of debate regarding the potential impacts of 97 98 TGD on the downstream river morphology, hydrology, and ecology, since the underlying mechanism of the impact of the TGD is not fully understood. Specifically, 99 100 the TGD's operation has altered the downstream fluvial discharge and water levels on 101 the seasonal scale, directly following the reservoir seasonal impounding and release of 102 water volume (e.g. Chen et al., 2016; Guo et al., 2018). However, the impacts of seasonal freshwater regulation by the TGD on the spatial-temporal tide-river dynamics 103 in the downstream estuarine area have not been systematically investigated. For 104 105 instance, during the dry season it was observed that the multi-year monthly averaged river discharge at Datong hydrological station was altered from 9520 m<sup>3</sup>·s<sup>-1</sup> to 12896 106 m<sup>3</sup>·s<sup>-1</sup> in January due to the operation of the TGD, while during the wet season the river 107 discharge was altered from 49900 m<sup>3</sup>·s<sup>-1</sup> to 44367 m<sup>3</sup>·s<sup>-1</sup> in July owing to the TGD's 108 109 regulation.

110

In this study, for the first time, the spatial-temporal variations in the hydrodynamic processes due to the interactions of tidal flow and fluvial discharge in the Yangtze River estuary caused by natural forcing and human intervention were studied, with specific focus on the TGD seasonal regulation effect. Here, we adopted a well-developed analytical model proposed by Cai et al. (2014a, 2016) to investigate the spatial-temporal

116	patterns of tide-river dynamics in the entire Yangtze River estuary and quantify the
117	impacts of the TGD's operation. In the following sections, we introduce the study site
118	of the Yangtze River estuary. This is followed by a description of the available data and
119	analytical model of tide-river dynamics in Section 3. Subsequently, we apply the model
120	to the Yangtze River estuary, where the TGD has operated since 2003 (Section 4). In
121	particular, we explore the alteration of the tide-river dynamics after the TGD closure
122	and summarise the impacts of the TGD on the spatial-temporal patterns of tide-river
123	dynamics. The impacts of channel geometry and river discharge alterations on tide-river
124	dynamics as well as the implications for sustainable water resource management are
125	then discussed in Section 5. Finally, some key findings are addressed in Section 6.

126

# 127 2. Overview of the Yangtze River estuary

The Yangtze River, flowing from west to east in central China, is one of the world's 128 most important rivers due to its great economic and social relevance. It has a length of 129 about 6300 km and a basin area of about 190,000 km<sup>2</sup> (Figure 1a). The Yangtze River 130 131 basin is geographically divided into three parts, the upper, central, and lower sub-basins, and contains an estuary area with partitions at Yichang, Jiujiang, and Datong (DT), 132 respectively (Figure 1a). Of concern in this study are the impacts of the Three Gorges 133 Dam (TGD), the world's largest dam, on the spatial-temporal patterns of tide-river 134 dynamics in the estuarine area. It is located about 45 km upstream of Yichang (Figure 135 1a). The TGD project began in 2003; by 2009, when full operations began, the total 136 water storage capacity rose up to ~40 km<sup>3</sup>, equivalent to 5% of the Yangtze's annual 137

138	discharge. Downstream of the DT station, where the tidal limit is located, the Yangtze
139	River estuary extends ~630 km to the seaward end of the South Branch. Wuhu (WH),
140	Maanshan (MAS), Nanjing (NJ), Zhenjiang (ZJ), Jiangyin (JY), and Tianshenggang
141	(TSG) are the major gauging stations along the mainstream in the seaward direction
142	(Figure 1b). Under the control of the Asian monsoon climate, river discharges show
143	distinct seasonal patterns. In 1979–2012, more than 70% of freshwater discharge at DT
144	occurred during summer (May–October).
145	

146	Apart from river flows, tidal waves are also recognised as the major sources of energy
147	for hydrodynamics in the Yangtze River estuary, which is characterised by a meso-tide
148	with a tidal range that extends up to $\sim$ 4.6 m and a mean tidal range of $\sim$ 2.7 m near the
149	estuary mouth. According to the observation in the Gaoqiaoju tidal gauging station
150	(1950–2012), the averaged ebb tide duration (7.5 h) is a bit longer than the averaged
151	flood tide duration (5 h), indicating an irregular semidiurnal character (Zhang et al.,
152	2012). Unlike previous studies focusing on tidal hydrodynamics near the estuary mouth,
153	or water and sediment alterations since the beginning of TGD's operation, here, we
154	mainly concentrate on the tide-river dynamics under the impacts of TGD seasonal
155	regulation over the entire reach of the Yangtze River estuary.

158 displaying the location of gauging and hydrological stations.

159

# 160 **3. Data and Methodology**

## 161 **3.1 Source of Data**

To quantitatively investigate the relationship between freshwater discharge regulation caused by the TGD's operation and the tide-river dynamics, monthly averaged hydrological data for both pre-TGD (1979–1984) and post-TGD (2003–2014) periods of tidal range and water level from the above-mentioned six tidal gauging stations along the Yangtze River estuary were collected. They were published by the Yangtze Hydrology Bureau of the People's Republic of China. The monthly averaged tidal

- amplitude is determined by averaging the daily difference of high and low water levels
- and a half. To correctly quantify the residual water level along the Yangtze estuary,
- 170 locally measured water levels of different gauging stations are corrected to the national
- 171 mean sea level of Huanghai 1985.
- 172

#### 173 **3.2 Analytical model for tide-river dynamics**

#### 174 **3.2.1 Basic equations**

In tidal rivers, the tidally averaged water level (i.e. residual water level) depicts a steady
gradient, which usually increases with freshwater discharge (e.g. Sassi and Hoitink,
2013). The key to deriving the dynamics of the residual water level lies in the onedimensional momentum equation, which can be expressed as (e.g. Savenije, 2005,
2012):

180 
$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + g \frac{\partial Z}{\partial x} + \frac{gh}{2\rho} \frac{\partial \rho}{\partial x} + g \frac{U |U|}{K^2 h^{4/3}} = 0, \qquad (1)$$

181 where *U* is the cross-sectional averaged velocity, *Z* is the free surface elevation, *h* is the 182 water depth, *g* is the acceleration due to gravity, *t* is the time,  $\rho$  is the water density, *x* is 183 the longitudinal coordinate directed landward, and *K* is the Manning-Strickler friction 184 coefficient. It was demonstrated that in the subtidal momentum balance, the residual 185 water level slope is primarily balanced by the residual friction term (Vignoli et al., 2003; 186 Buschman et al., 2009; Cai et al., 2014a, for a detailed derivation, readers can refer to 187 the Appendix A):

188 
$$\frac{\overline{\partial Z}}{\partial x} = -\frac{\overline{U \mid U \mid}}{K^2 h^{4/3}}$$
(2)

189

- where the overbars indicate the tidal average. For a single channel with the residual water level set to 0 at the estuary mouth (i.e.  $\overline{Z} = 0$  at x = 0), the integration of Equation (2) leads to an analytical expression for the residual water level
- 193  $\overline{Z}(x) = -\int_{0}^{x} \frac{\overline{\partial Z}}{\partial x} = -\int_{0}^{x} \frac{\overline{U|U|}}{K^{2}h^{4/3}}$  (3)

To derive the analytical solutions for tide-river dynamics, we assume that the longitudinal variation of cross-sectional area  $\overline{A}$  and width  $\overline{B}$  can be described by the following exponential functions (see also Toffolon et al., 2006; Cai et al., 2014a):

197 
$$\overline{A} = \overline{A_r} + \left(\overline{A_0} - \overline{A_r}\right) \exp\left(-\frac{x}{a}\right), \tag{4}$$

198 
$$\overline{B} = \overline{B_r} + \left(\overline{B_0} - \overline{B_r}\right) \exp\left(-\frac{x}{b}\right), \tag{5}$$

where  $\overline{A_0}$  and  $\overline{B_0}$  represent the tidally averaged cross-sectional area and width at the 199 estuary mouth, respectively,  $\overline{A_r}$  and  $\overline{B_r}$  represent the asymptotic riverine cross-200 sectional area and width, respectively, and a and b are the convergence lengths of the 201 cross-sectional area and width, respectively. The advantage of these equations for 202 203 approximating the shape of the estuary is that they account not only for the exponential shape in the lower part of the tidal river but also for the approximately prismatic channel 204 in the upstream part of the tidal river. We further assume a nearly rectangular cross-205 section; hence, the tidally averaged depth is given by  $\bar{h} = \bar{A}/\bar{B}$ . 206

#### 207 3.2.2 Analytical solution for tidal hydrodynamics

It was shown by Cai et al. (2014a, b, 2016) that the tide-river dynamics is dominantly controlled by four dimensionless parameters (see their definitions in Table 1). They include: the dimensionless tidal amplitude  $\zeta$  (representing the boundary condition in the

211	seaward side), the estuary shape number $\gamma$ (representing the cross-sectional area
212	convergence), the friction number $\chi$ (representing the bottom frictional effect), and the
213	dimensionless river discharge $\varphi$ (representing the impact of freshwater discharge),
214	where $\eta$ is the tidal amplitude, $v$ is the velocity amplitude, $U_r$ is the river flow velocity,
215	$\omega$ is the tidal frequency, $r_S$ is the storage width ratio accounting for the effect of storage
216	area (i.e. tidal flats or salt marshes), and $c_0$ is the classical wave celerity defined as
217	$c_0 = \sqrt{g \bar{h} / r_s} \ .$

# 218 Table 1. Definitions of dimensionless parameters used in the analytical model

Local variables	Dependent variables
Dimensionless tidal amplitude	Amplification number
$\zeta = \eta  /  \overline{h}$	$\delta = c_0 \mathrm{d}\eta / \left(\eta \omega \mathrm{d}x\right)$
Estuary shape number	Velocity number
$\gamma = c_0 \left(\overline{A} - \overline{A_r}\right) / \left(\omega a \overline{A}\right)$	$\mu = \upsilon / (r_s \zeta c_0) = \upsilon \overline{h} / (r_s \eta c_0)$
Friction number	Celerity number
$\chi = r_{s}gc_{0}\zeta \left[1 - \left(4\zeta / 3\right)^{2}\right]^{-1} / \left(\omega K^{2}\overline{h}^{4/3}\right)$	$\lambda = c_0 \ / \ c$
Dimensionless river discharge	Phase lag
$\phi = U_r / \upsilon$	$\varepsilon = \pi / 2 - (\phi_z - \phi_u)$

219

In this study, we used the analytical solutions proposed by Cai et al. (2014a, b, 2016), in which the solutions of the major tide-river dynamics are derived by solving a set of four implicit equations for the tidal damping, the velocity amplitude, the wave celerity, and the phase lag (see details in Appendix B). The major dependent parameters can be

224 described by the following four variables (see also Table 1):  $\delta$  represents the damping/amplification number describing the increase ( $\delta > 0$ ), or decrease ( $\delta < 0$ ) of 225 the tidal wave amplitude along the estuary axis,  $\mu$  represents the velocity number 226 indicating the ratio of actual velocity amplitude to the frictionless value in a prismatic 227 228 channel,  $\lambda$  represents the celerity number representing the classical wave celerity  $c_0$ scaled by the actual wave celerity c, and  $\varepsilon$  represents the phase lag between the high 229 230 water (HW) and high water slack (HWS) or between the low water (LW) and low water 231 slack (LWS). It is important to note that the phase lag (ranging between 0 and  $\pi/2$ ) is a 232 key parameter in classifying the estuary, where  $\varepsilon = 0$  suggests the tidal wave is featured by a standing wave, while  $\varepsilon = \pi/2$  indicates a progressive wave. For a simple harmonic 233 wave, the phase lag is defined as  $\varepsilon = \pi / 2 - (\phi_z - \phi_u)$ , where  $\phi_z$  and  $\phi_u$  are the phases of 234 235 elevation and current, respectively (Savenije, et al., 2008).

#### 236 3.2.3 Analytical solution for the entire channel

It is worth noting that the analytically computed tide-river dynamics  $\mu$ ,  $\delta$ ,  $\lambda$ , and  $\varepsilon$  only 237 represent local hydrodynamics since they depend on local (fixed position) values of the 238 239 dimensionless parameters, i.e. the tidal amplitude  $\zeta$ , the estuary shape number  $\gamma$ , the friction number  $\chi$ , and the river discharge  $\varphi$  (see Table 1). To correctly reproduce the 240 tide-river dynamics for the entire channel, a multi-reach technique is adopted by 241 subdividing the entire estuary into multiple reaches to account for the longitudinal 242 243 variations of the estuarine sections (e.g. bed elevation, bottom friction). For a given tidal damping/amplification number  $\delta$  and tidal amplitude  $\eta$  at the seaward boundary, it 244 is possible to determine the tidal amplitude at a distance  $\Delta x$  (e.g. 1 km) upstream by 245

- simple explicit integration. Hence, the analytical solution for the entire channel can be
- 247 obtained by step-wise integration in this way.
- 248
- 249 **4. Results**

## 250 4.1 Alteration of the tide-river dynamics after TGD closure

To quantify the impacts of TGD's operation on the downstream tide-river dynamics, 251 252 we divided the time series into two periods, including a pre-TGD period (1979–1984, 253 representing the condition before the operation of the TGD) and a post-TGD period 254 (2003–2014, after the closure of the TGD with an operating TGD). Figure 2 shows the changes in the observed tidal range  $\Delta H$  and residual water level  $\Delta \overline{Z}$  before and after 255 the closure of the TGD at the six gauging stations, together with the change in 256 257 freshwater discharge  $\Delta Q$  observed at the DT hydrological station. Figure 2 and Table 2 258 clearly show that the monthly averaged river discharge in January, February, and March substantially increased by 35.5%, 30.5%, and 16.4%, respectively, due to the 259 considerable release of freshwater from the TGD. On the other hand, we observe a 260 261 significant decrease in freshwater discharge in September, October, and November, decreasing by 20.1%, 33.2%, and 20.8%, respectively. The reason can be primarily 262 attributed to the impounding water of the TGD during these months, especially in 263 October. During the other months, the impacts of TGD on the change in the freshwater 264 265 discharge are relatively small, mimicking the natural condition before the operation of the TGD. 266

267

268	In Figure 2a we observe an increasing trend in tidal range for the post-TGD period at
269	the six gauging stations, except for the marked decrease at the ZJ station in the first half
270	of the year (i.e. January-June). On average, the maximum increase (0.20 m) in tidal
271	range occurs in October, which is mainly due to the substantial reduction of river
272	discharge caused by the TGD's operation. This indicates a consistent enhancement of
273	tidal dynamics along the Yangtze estuary, except the reach near the ZJ station. For the
274	residual water level, Figure 2b clearly shows that the change in the residual water level
275	directly follows that of the river discharge due to the stable relationship between these
276	two parameters. In particular, we see that the residual water levels increased by 0.26 m,
277	0.30 m, and $0.16$ m, respectively, in January, February, and March, while they
278	significantly decreased by 0.72 m, 1.17 m, and 0.70 m, respectively, in September,
279	October, and November. In addition, the decrease trend in residual water level is more
280	significant in upstream stations when compared with those in the downstream areas.

Figure 2. Changes in monthly averaged (a) tidal range  $\Delta H$  and (b) residual water level

283  $\Delta \overline{Z}$  together with the freshwater discharge  $\Delta Q$  along the Yangtze River estuary.

284

Table 2. Comparison of multi-year monthly averaged river discharge Q (m<sup>3</sup>·s<sup>-1</sup>)

Month	1	2	3	4	5	6	7	8	9	10	11	12

286 between the pre-TGD and the post-TGD periods

287

288 Since the TGD's operation affects tide-river dynamics primarily through the alteration

289 of the freshwater discharge, it is worth exploring the patterns of trends in the

relationship between the freshwater discharge and gradients of the main tidal parameters with respect to distance (i.e. the tidal damping rate and the residual water level slope). Here, we estimated the tidal damping rate  $\delta_H$  and the residual water level slope *S* for a reach of  $\Delta x$  by using the following expressions:

294 
$$\delta_{H} = \frac{1}{(H_1 + H_2)/2} \frac{H_2 - H_1}{\Delta x},$$
 (6)

$$S = \frac{\overline{Z_2} - \overline{Z_1}}{\Delta x},$$
(7)

296 where  $H_1$  and  $\overline{Z_1}$  are the tidal amplitude and residual water level on the seaward side, respectively, whereas  $H_2$  and  $\overline{Z_2}$  are the corresponding values  $\Delta x$  upstream, 297 298 respectively. Figure 3 presents the computed tidal damping rates for different reaches along the Yangtze estuary based on the observed tidal ranges at the six gauging stations. 299 It is remarkable that the tidal damping rates at the ZJ-NJ and MAS-WH reaches have 300 301 significantly increased during the post-TGD period, which suggests an enhancement of 302 tidal dynamics under the current freshwater discharge conditions. On the contrary, a noticeable decrease in  $\delta_H$  was observed at the JY-ZJ reach, which corresponds to a 303 decrease in tidal range at the ZJ station for the low river discharge conditions (from 304 305 January to May, see Figure 2a). At TGS-JY and NJ-MAS, no significant change in  $\delta_H$ is observed. In Figure 4, a consistent decrease in the residual water level slope S is 306 observed along the Yangtze estuary, except for the JY-ZJ reach. This means that the 307 residual friction effect becomes weaker in the post-TGD period since the residual water 308 309 level slope is primarily balanced by the residual friction term (Cai et al., 2014a, b, 2016).

Figure 3. Changes in tidal damping rate  $\delta_H$  before and after the TGD closure for different reaches along the Yangtze estuary: (a) TGS-JY, (b) JY-ZJ, (c) ZJ-NJ, (d) NJ-MAS, (e) MAS-WH.

Figure 4. Changes in residual water level slope *S* before and after the TGD closure for
different reaches along the Yangtze estuary: (a) TGS-JY, (b) JY-ZJ, (c) ZJ-NJ, (d) NJMAS, (e) MAS-WH.

318

## 319 **4.2** Performance of the analytical model reproducing the tide-river dynamics

The analytical model presented in Section 3.2 was subsequently applied to the Yangtze River estuary, with the seaward boundary using the tidal amplitude imposed at the TSG station and the landward boundary using the river discharge imposed at the DT station. The computation length of the estuary is 470 km, covering the entire estuary from TSG to DT. The adopted geometric characteristics (including the tidally averaged crosssectional area, width, and depth) are the same for both pre- and post-TGD periods, which were extracted from a digital elevation model (DEM) using Yangtze River

327	estuary navigation charts surveyed in 2007. The geometric characteristics, calibrated
328	by fitting the observed values using Equations (4) and (5), are presented in Table 3,
329	where a relatively large cross-sectional area convergence length ( $a = 151$ km) is evident,
330	with a relatively small width ( $b = 44$ km), indicating a fast transition from a funnel-
331	shaped reach to a prismatic reach in terms of width. It is worth noting that the Yangtze
332	River estuary is characterised by a typical semidiurnal character; thus, a typical M2 tidal
333	period (i.e. 12.42 h) was adopted in the analytical model. For the sake of simplification,
334	we assume that the storage width ratio $r_S = 1$ . Hence, the only calibrated parameter is
335	the Manning-Strickler friction coefficient K. Here, we used two values for $K$ : $K = 80$
336	m <sup>1/3</sup> ·s <sup>-1</sup> in the tide-dominated region ( $x = 0-42$ km), and a smaller value of $K = 55$
337	m <sup>1/3</sup> ·s <sup>-1</sup> in the river-dominated region ( $x = 42-450$ km). The analytically computed
338	results were compared with the observed tidal amplitudes and the residual water levels
339	at five gauging stations along the Yangtze estuary (Figure 5). It can be seen that the
340	overall correspondence between analytical results and observations is good, with high
341	coefficients of determination ( $R^2 > 0.95$ ), which suggests the usefulness of the present
342	analytical model for reproducing the tide-river dynamics, given the gross features of
343	flow characteristics and estuarine geometry.

344

Table 3. Characteristics of geometric parameters in the Yangtze River estuary

Characteristics	River	Mouth	Convergence length $a/b$ (km)
Cross-sectional area $\bar{A}$ (m <sup>2</sup> )	12,135	51,776	151
Width $\overline{B}$ (m)	2005	6735	44

346

Figure 5. Comparison of analytically computed tidal amplitude  $\eta$  (a, b) and residual water level  $\overline{Z}$  (c, d) against the observations in the Yangtze River estuary for the pre-TGD period (1979–1984) and post-TGD period (2003–2014).

350

## 351 4.3 Impacts of TGD's operation on spatial-temporal patterns of tide-river

352 dynamics

With the significant seasonal discharge variations resulting from the TGD regulation, an understanding of the seasonal impacts on tide-river dynamics along the estuary has become increasingly important. In Figures 6 and 7, we see how the TGD's operation impacts the longitudinal variation of the main tidal dynamics in terms of the four dependent parameters  $\delta$ ,  $\lambda$ ,  $\mu$ , and  $\varepsilon$  for different seasons. The most considerable changes in the major tide-river dynamics occurred in both autumn and winter seasons, which correspond to the substantial reduction in freshwater discharge in the wet-to-dry

transition period (i.e. autumn) and slightly increased freshwater discharge in the dry 360 361 season (i.e. winter) due to the TGD's operation since 2003 (see Table 2). On the other hand, the impacts of the TGD's operation on the tide-river dynamics during the spring 362 and summer are relatively minor due to the negligible change in the freshwater 363 364 discharge. However, we do notice that the TGD had exerted slight influence on tideriver dynamics in the downstream reaches (x < 250 km) during the summer, with the 365 366 maximum freshwater discharge occurring within a year. In addition, it appears that there 367 exists a critical position corresponding to the maximum tidal damping (or minimum 368 value of  $\delta$ ) upstream in which the tidal damping becomes weak. This phenomenon occurs particularly in the spring, summer, and autumn. The underlying mechanism is 369 elaborated in the discussion section. 370

371

372 Figures 6a, c, e, g show the comparison of the analytically computed tidal damping number  $\delta$  before and after the closure of the TGD, in which we clearly identify that the 373 longitudinal tidal damping effect was considerably weakened in autumn, while it was 374 375 slightly enhanced in winter after the TGD closure. This was expected since freshwater discharges tend to dampen the tidal wave primarily through the enhancement of the 376 friction term (Horrevoets et al., 2004; Cai et al., 2014a, b, 2016). Figures 6b, d, g, i 377 show a similar picture for the wave celerity number  $\lambda$ , which is positively correlated to 378 379 the tidal damping number  $\delta$ , according to the celerity equation (11) in Appendix B. Figure 7 shows the longitudinal computation of the velocity number  $\mu$  and the phase 380 lag  $\varepsilon$  for both periods. The impacts of the TGD's operation on the velocity scale and 381

- 382 phase lag are similar to the tidal damping, i.e. the larger the freshwater discharge is, the
- 383 smaller the velocity number and the phase lag are.
- 384
- Overall, in the seaward reach of the estuary, the effect of freshwater discharge alteration 385 386 by the TGD's operation on the major tide-river dynamics (i.e.  $\delta$ ,  $\lambda$ ,  $\mu$ , and  $\varepsilon$ ) was less significant because of the small ratio of freshwater discharge to tidal discharge. On the 387 388 other hand, in the upstream reach of the estuary, the changes in the four dependent 389 parameters are also small due to the substantial tidal attenuation as a result of the long-390 distance propagation from the estuary mouth. Therefore, the pattern of seasonal 391 variation due to the TGD's operation is relatively small at both ends of the estuary, whereas the largest variation usually occurs in the middle reach of the estuary. This 392 393 finding was supported by the results of harmonic analysis using the numerical results 394 (Zhang et al., 2018). Similar phenomena have also been identified in other large fluvial meso-tide estuaries, such as the Mekong River estuary and Amazon River estuary, 395 where dam operation altered the seasonal patterns of tide-river dynamics (Kosuth et al., 396 397 2009; Hecht et al., 2018).
- 398

408

# 409 5. Discussion

## 410 5.1 The impact of channel geometry alteration on tide-river dynamics

411 Dam operations, which dramatically modified downstream flow and sediment regimes,

- 412 are becoming an increasingly important factor controlling the morphological evolution.
- 413 Previous studies show that, as a result of the trapping of sediments by the TGD,
- 414 considerable erosion occurred in the first several hundred km downstream of the TGD,

415	considerably coarsening the bedload (Yang et al., 2014). In particular, the river
416	immediately downstream eroded at a rate of 65 Mt/yr in 2001–2002 (Yang et al., 2014).
417	It was shown by Lyu et al. (2018) that due to a dramatic reduction in the sediment
418	discharge following the construction of the TGD, a significant change in size, geometry,
419	and spatial distribution of pool-riffles occurred downstream; however, this adjustment
420	was limited to the reaches close to the TGD. It should be noted that the bathymetry
421	adopted in the analytical model is restricted to the estuarine area in 2007, which is only
422	4 years after the TGD closure in 2003, and it is before the full operation of the TGD
423	began in 2009. In addition, the TGD is around 1600 km away from the estuary mouth,
424	and its influence on the estuarine morphology normally has a lag effect of at least 4-5
425	years, as discussed by Wang et al. (2008). Hence, the adopted geometry has been only
426	partly altered after the TGD closure. Consequently, we concluded that the impact of the
427	channel geometry alteration on tide-river dynamics in the Yangtze River estuary is
428	limited and, thus, the correspondence with the observed tidal amplitude and residual
429	water level for the pre-TGD period is good, such that we even used the geometry
430	surveyed in 2007.

# 431 **5.2** The impact of freshwater discharge alteration on tide-river dynamics

432

The water conservancy of the TGD has multiple purposes, in which the seasonal discharge regulation and their impact on the ecosystem are well documented (e.g. Mei et al., 2015a, b; Chen et al., 2016; Guo et al., 2018). However, the actual influence of discharge regulation on the river-tide dynamics in the estuarine area is not fully

437	understood. With the analytical reproduction of tide-river dynamics for pre- and post-
438	TGD periods, it is possible to quantify the extent of the changes in the major tidal
439	dynamics, including the estuary shape number $\gamma$ and friction number $\chi$ (Figure 8), and
440	the residual water level slope $S$ and water depth $h$ (Figure 9) along the Yangtze River
441	estuary. In general, during the transition from the wet season (summer-autumn) to the
442	dry season (winter-spring), the water level and corresponding fluvial discharge
443	downstream from the TGD is first raised by the impounding water and then reduced by
444	the release of water, which would substantially change the tide-river dynamics in the
445	downstream estuarine area, with the maximum variation occurring in autumn and the
446	minimum variation occurring in spring.

447

448

Figure 8. Longitudinal variability of simulated estuary shape number  $\gamma$  (a, c, e, g) and friction number  $\chi$  (b, d, g, i) along the Yangtze estuary in different seasons (spring: a, b; summer: c, d; autumn: e, g; winter: g, i) for both the pre-TGD and the post-TGD periods.

452

453

Figure 9. Longitudinal variability of simulated residual water level slope S (a, c, e, g)
and water depth h (b, d, g, i) along the Yangtze estuary in different seasons (spring: a,
b; summer: c, d; autumn: e, g; winter: g, i) for both the pre-TGD and the post-TGD
periods.

458

Figures 8 and 9 show that during the wet season (summer-autumn), the estuary shape number  $\gamma$  and friction number  $\chi$  experience a general increase, while a decrease in the residual water level slope *S* and water depth  $\bar{h}$  can be identified in the post-TGD period due to the reduction in freshwater discharge. However, the changes in these major dynamics vary significantly along the channel. Near the estuary mouth, where

464	the tidal influence dominates that of the freshwater discharge, the difference is
465	relatively small, as the magnitude of the freshwater discharge is small when compared
466	with that of the tidal discharge. Meanwhile at the upstream reach of the estuary, where
467	the riverine influence dominates that of the tide, the difference is also small due to the
468	attenuation of the tidal wave propagation over a long distance. Consequently, the most
469	significant changes in major tide-river dynamics occurred in the middle reach of the
470	Yangtze River estuary due to the discharge regulation of the TGD during the wet season.
471	By contrast, during the dry season (winter-spring), especially in winter, the opposite
472	trend was observed, indicating a slight increase in $\gamma$ and $\chi$ , and a slight decrease in S
473	and $\bar{h}$ due to the additional release of discharge from the TGD. In addition, we also
474	observed that the changes in tide-river dynamics caused by the TGD's operation were
475	much stronger upstream than in the lower stream.

476

# 477 5.3 Implications for water resource management

478 The construction of the TGD is the largest hydro-development project ever performed

479 in the world, having multiple influences on downstream water resource management,

480 including navigation, flood control, tidal limit variation, and salt intrusion.

# 481 5.3.1 Implications for navigation

The navigation condition is mainly controlled by both high water and low water levels. Figure 10 shows the estimation of the cumulative distribution function (cdf) for both the high-water level (Figure 10a) and the low-water level (Figure 10b) at the six gauging stations along the Yangtze River estuary for both the pre- and post-TGD

periods. The results indicate that navigation conditions during the non-flood season are 486 generally improved, because both percentages of high-water and low-water levels are 487 increased due to the additional freshwater discharge released from the TGD. On the 488 other hand, during the flood season, the reduction in the freshwater discharge by TGD 489 490 impounding tends to exert a negative impact on navigation. However, the reduced freshwater discharges in the late summer and autumn are not of sufficient magnitude to 491 492 cause any navigation problems. This is due to the fact that the mean water levels during 493 the flood season are relatively high; hence, the regulating flow quantity and regulating 494 capacity are relatively small (e.g. Chen et al., 2016). In general, due to the staggered regulation in freshwater discharge, seasonally, the actual navigation condition is 495 improved due to the significant increase in the percentage of low water levels. 496

497

498 Figure 10. Cumulative distribution function (cdf) estimated by using the kernel

- 499 smoothing function for high water level (a) and low water level (b) at six gauging
- stations along the Yangtze estuary. The drawn lines represent the pre-TGD period, while
- 501 the dashed lines represent the post-TGD period.

# 502 5.3.2 Implications for flood control

Flood control is one of the most important functions of building dams and reservoirs in 503 large rivers. Before the construction of the TGD, the Yangtze River basin suffered from 504 frequent and disastrous flood threats. For instance, the floods of 1998 in the Yangtze 505 506 River were reported to have killed 3656 people, destroyed 5.7 million homes, and 507 damaged seven million more. Many studies have examined the flood control capacity 508 of the TGD over the past two decades (Zhao et al., 2013; Chen et al., 2014). In particular, 509 the capability of the TGD flood control is influenced by multiple factors (e.g. Huang et al., 2018), particularly in the estuarine area, which is strongly influenced by tides from 510 the ocean. During the flood season, the reduced freshwater discharge by TGD 511 512 impounding benefits the flood control by reducing the peak flood discharge. However, as the tidal influence is enhanced, both the percentages of high water and low water 513 514 levels for the post-TGD period are considerably increased, as shown in Figure 10, indicating a decreased flood control capability. For instance, at the WH gauging station 515 located in the upstream part of the Yangtze River estuary, the 8-m high-water level 516 increased by approximately 10% after the TGD closure during the wet season. The 517 corresponding flood prevention standard, therefore, is reduced from the 20-year return 518 period to the 10-year return period due to the increased high-water level. 519

#### 520 5.3.3 Implications for tidal limit

521 It is important to detect the position of the tidal limit (corresponding with the position 522 where the tidal amplitude to depth ratio is less than a certain threshold, e.g.  $\frac{\eta}{h} < 0.02$ ),

523	which is the farthest point upstream where a river is affected by tidal fluctuations, since
524	it is essential for surveying, navigation, and fisheries management, in general (e.g. Shi
525	et al., 2018). Subsequently, we are able to define the tide-influenced length as the
526	distance upstream from the estuary mouth to the tidal limit. Generally, the tidal limit
527	fluctuates with the changes in the seasonal freshwater discharges. Field measurements
528	have demonstrated that tidal limit can reach as far as the NJ station and further upstream
529	during the dry season, while during the wet season, it is pushed down to the ZJ station
530	and may be pushed further downward to the JY station under spate conditions. Figure
531	11 shows the analytically computed tidal limit position for both the pre- and post-TGD
532	periods. It can be observed that the tidal limit moved downstream by about 25 km and
533	250 km in January and December under the impact of the additional release of discharge
534	from TGD during the dry season. During the transition from dry to wet seasons
535	(January-May), the total freshwater discharge from TGD increases, and we identify
536	further downstream movement of the tidal limit, although to a smaller extent. The
537	reverse of the post-TGD tidal limit in April is due to the decrease in the freshwater
538	discharge compared with the pre-TGD tidal limit (see Table 2). The TGD storage period
539	begins in June, and the tidal limit moved upstream by a large amount compared with
540	the pre-TGD period. The largest change occurred during October when the tidal limit
541	moved from 175 km pre-TGD to 225 km post-TGD due to the substantial increase in
542	freshwater discharge (see Table 2).

Figure 11. Temporal variation of the position of the tidal limit relative to the TSG station
for both the pre-TGD and the post-TGD periods.

#### 546 5.3.4 Implications for salt intrusion

The operation of the TGD changed the location of tidal limit, which, in turn, directly 547 548 influences the intensity of saltwater intrusion, especially during the dry season, when the freshwater discharge is low and saltwater intrusion is important (e.g. Cai et al., 549 2015). The analysis of tide-river dynamics shows that the tidal dynamics are 550 considerably enhanced during the autumn due to the substantial decline in freshwater 551 552 discharged into the estuary, which may lead to enhanced saltwater intrusion. However, with supplemented discharge after the TGD during the winter, saltwater intrusion tends 553 to be significantly suppressed, and the isohalines are pushed seaward by additional river 554 discharges (e.g. An et al., 2009; Qiu and Zhu, 2013). In contrast, during the wet season, 555

- the TGD's operation slightly extended the timing of saltwater intrusion and increased its intensity by impounding freshwater. Since the total river discharge rate during the wet season is the largest during the year, the influence of saltwater on freshwater reservoirs along the coastal area is limited. Therefore, the operation of TGD is overall favourable for reducing the burden of freshwater supplement in the tidally influenced estuarine areas.
- 562 6. Conclusions

563 An analytical approach was used to examine the potential impacts of TGD's operation 564 on the spatial-temporal patterns of tide-river dynamics along the Yangtze River estuary. It was shown that the freshwater regulation caused by the TGD, on a seasonal scale, 565 exerts significant impacts on the tide-river dynamics, with the maximum influence 566 567 occurring in autumn and winter. This generally corresponds to a dramatic decrease in 568 freshwater discharge during the wet-to-dry transition period and a slight increase in discharge during the dry season. The analytical results indicate that the discharge 569 regulation by the TGD drives the alterations in the tide-river dynamics instead of the 570 571 geometric change. In particular, the change in the freshwater discharge changes the estuary shape number (representing the geometric effect), the residual water level slope 572 (representing the effective frictional effect) and, hence, the tide-river dynamics. This 573 study, using the Yangtze River estuary as a significant case study, provides an effective 574 575 yet simple method to quantify the seasonal regulation in freshwater discharge by large reservoirs or dams on hydrodynamics in estuaries. The results obtained from this study 576 will, hopefully, shed new light on aspects of water resource management, such as 577

- 578 navigation, flood control, and salt intrusion.

#### 700 Appendix A. Simplified momentum balance for the residual water level slope

Assuming a periodic variation of flow velocity, the integration of Equation (1) over a
tidal cycle leads to an expression for the residual water level slope (e.g. Cai et al., 2014a,
2016):

704 
$$\frac{\partial \overline{Z}}{\partial x} = -\frac{1}{K^2} \overline{\left(\frac{U | U |}{h^{4/3}}\right)} - \frac{1}{2g} \frac{\partial \overline{U^2}}{\partial x} - \frac{1}{2\rho_0} \overline{h} \frac{\partial \rho}{\partial x}$$
(8)

where the overbars and the subscript 0 indicate the tidal average and value at the seaward boundary, respectively. The residual water level slope is induced by three contributions: residual frictional, advective acceleration, and density effects, which correspond to the three terms on the right-hand side of Equation (8). Note that the contribution from advective acceleration to the residual water level slope:

710 
$$\frac{\partial \overline{Z}_{adv}}{\partial x} = -\frac{1}{2g} \frac{\partial \overline{U^2}}{\partial x},$$
 (9)

711 can be easily integrated to:

712 
$$\overline{Z}_{adv} = -\frac{1}{2g} \left( \overline{U^2} - \overline{U_0^2} \right) = -\frac{1}{2} \overline{Fr_0} \left( \frac{U^2}{\overline{U_0^2}} - 1 \right) \overline{h_0}$$
(10)

where the Froude number is introduced,  $\overline{Fr^2} = \overline{U^2}/(g\overline{h})$ , which is computed with the 713 averaged variables. In this case, the correction is local (not cumulative) and 714 715 proportional to the flow depth through a coefficient that is negligible as long as the 716 velocity does not change significantly, and Fr is small, as is common in most tidal flows. 717 It was shown by Savenije (2005, 2012) that the density term in equation (1) always exercises a pressure in the landward direction, which is counteracted by a residual water 718 level slope, amounting to 1.25% of the estuary depth over the salt intrusion length. The 719 720 value for the residual water level slope, induced by the density effect, is usually small compared with the gradient of the free surface elevation; thus, in this paper, we neglect 721 the influence of the density difference on the dynamics of the residual water level. 722

723

## 724 Appendix B. Governing equations for tide-river dynamics in estuaries

The analytical solutions for the dependent parameters  $\mu$ ,  $\delta$ ,  $\lambda$ , and  $\varepsilon$  are obtained by solving the following four dimensionless equations (see details in Cai et al., 2014a):

the tidal damping/amplification equation, describing the tidal amplification or damping as a result of the balance between channel convergence (gq) and bottom friction (cm/G):

730 
$$\delta = \frac{\mu^2 \left( \gamma \theta - \chi \mu \lambda \Gamma \right)}{1 + \mu^2 \beta}, \tag{11}$$

733

- the scaling equation, describing how the ratio of velocity amplitude to tidal amplitude
- 732 depends on phase lag and wave celerity:

$$\mu = \frac{\sin(\varepsilon)}{\lambda} = \frac{\cos(\varepsilon)}{\gamma - \delta},\tag{12}$$

the celerity equation, describing how the wave celerity depends on the balance between

735 convergence and tidal damping/amplification:

736 
$$\lambda^2 = 1 - \delta(\gamma - \delta), \tag{13}$$

737 and the phase lag equation, describing how the phase lag between HW and HWS

738 depends on wave celerity, convergence, and damping:

739 
$$\tan\left(\varepsilon\right) = \frac{\lambda}{\gamma - \delta},\tag{14}$$

740 where q, b, and G account for the effect of river discharge and where:

741 
$$\beta = \theta - r_s \zeta \varphi / (\mu \lambda), \quad \theta = 1 - \left(\sqrt{1 + \zeta} - 1\right) \varphi / (\mu \lambda), \quad \Gamma = \frac{1}{\pi} \left[ p_1 - 2p_2 \varphi + p_3 \varphi^2 \left(3 + \mu^2 \lambda^2 / \varphi^2\right) \right].$$
742 (15)

743 Note that  $\Gamma$  is a friction factor obtained by using Chebyshev polynomials (Dronkers,

1964) to represent the non-linear friction term in the momentum equation:

745 
$$F = \frac{U |U|}{K^2 \bar{h}^{4/3}} \approx \frac{1}{K^2 \bar{h}^{4/3} \pi} \left( p_0 \upsilon^2 + p_1 \upsilon U + p_2 U^2 + p_3 U^3 / \upsilon \right)$$
(16)

in which U is the cross-sectional averaged velocity consisting of a steady component  $U_r$ , generated by the fresh water discharge, and a time-dependent component  $U_t$ , introduced by the tide:

749  $U = U_t - U_r = \upsilon \sin(\omega t) - Q / \overline{A}$ (17)

where Q is the fresh water discharge (treated as a constant during the tidal wave propagation), and  $p_i$  (I = 0, 1, 2, 3) are the Chebyschev coefficients (see Dronkers, 1964, p. 301), which are functions of the dimensionless river discharge  $\varphi$  through  $\alpha$  = arcos(- $\phi$ ):

754 
$$p_0 = -\frac{7}{120}\sin(2\alpha) + \frac{1}{24}\sin(6\alpha) - \frac{1}{60}\sin(8\alpha), \qquad (18)$$

755 
$$p_1 = \frac{7}{6}\sin(\alpha) - \frac{7}{30}(3\alpha) - \frac{7}{30}\sin(5\alpha) + \frac{1}{10}\sin(7\alpha), \qquad (19)$$

756 
$$p_2 = \pi - 2\alpha + \frac{1}{3}\sin(2\alpha) + \frac{19}{30}\sin(4\alpha) - \frac{1}{5}\sin(6\alpha), \qquad (20)$$

757 
$$p_3 = \frac{4}{3}\sin(\alpha) - \frac{2}{3}\sin(3\alpha) + \frac{2}{15}\sin(5\alpha).$$
(21)

The coefficients  $p_1$ ,  $p_2$ , and  $p_3$  determine the magnitudes of the linear, quadratic, and

759 cubic frictional interaction, respectively.
