

27 **Abstract**

28 The processes that contribute to the flat Sea Surface Height (SSH) wavenumber spectral slopes
29 observed in the tropics by satellite altimetry are examined in the tropical Pacific. The tropical
30 dynamics are first investigated with a $1/12^\circ$ global model. The equatorial region from $10^\circ\text{N} - 10^\circ\text{S}$ is
31 dominated by Tropical Instability Waves with a peak of energy at 1000 km wavelength, strong
32 anisotropy, and a cascade of energy from 600 km down to smaller scales. The off-equatorial regions
33 from $10\text{-}20^\circ$ latitude are characterized by a narrower mesoscale range, typical of mid latitudes. In the
34 tropics, the spectral taper window and segment lengths need to be adjusted to include these larger
35 energetic scales. The equatorial and off-equatorial regions of the $1/12^\circ$ model have surface kinetic
36 energy spectra consistent with quasi-geostrophic turbulence. The balanced component of the
37 dynamics slightly flatten the EKE spectra, but modeled SSH wavenumber spectra maintain a steep
38 slope that does not match the observed altimetric spectra. A second analysis is based on $1/36^\circ$ high-
39 frequency regional simulations in the western tropical Pacific, with and without explicit tides, where
40 we find a strong signature of internal waves and internal tides that act to increase the smaller-scale
41 SSH spectral energy power and flattening the SSH wavenumber spectra, in agreement with the
42 altimetric spectra. The coherent M2 baroclinic tide is the dominant signal at ~ 140 km wavelength. At
43 short scales, wavenumber SSH spectra are dominated by incoherent internal tides and internal waves
44 which extend up to 200 km in wavelength. These incoherent internal waves impact on space scales
45 observed by today's alongtrack altimetric SSH, and also on the future SWOT 2D swath observations,
46 raising the question of altimetric observability of the shorter mesoscale structures in the tropics.

47

48

49 **1. Introduction**

50 Recent analyses of global sea surface height (SSH) wavenumber spectra from alongtrack altimetric
51 data (Xu and Fu, 2011, 2012; Zhou et al., 2015) have found that while the mid-latitude regions have
52 spectral slopes consistent with quasi-geostrophic (QG) theory or surface quasi-geostrophic (SQG)
53 theory, the tropics were noted as regions with very flat spectral slopes (Fig. 1a). The objective of this
54 paper is to better understand the processes specific to the tropics that contribute to the SSH
55 wavenumber spectral slopes observed by satellite altimetry, particularly in the “mesoscale” range at
56 scales < 600 km, 90 days (Tulloch et al., 2009).

57
58 Only a few studies have addressed the tropical dynamics at spatial scales smaller than this 600 km
59 cutoff wavelength. The tropics are characterized by a large latitude-dependent Rossby deformation
60 radius (L_d) varying from 80 km at 15° to 250 km in the equatorial band. Different studies have clearly
61 distinguished the tropical regions dominated by linear planetary waves from the mid-latitudes
62 dominated by non-linear regimes (Fu, 2004; Theiss, 2004; Chelton, 2007). Close to the equator,
63 baroclinic instability is inhibited while barotropic instability becomes more important (Qiu and Chen
64 2004), and mesoscale structures arise from the baroclinic and barotropic instabilities associated with
65 the vertical and horizontal shears of the upper circulation (Ubelmann and Fu, 2011; Marchesiello et
66 al., 2011). This distinct regime in the tropics raises many questions on the representation of the
67 meso/submesoscale tropical dynamics in the global analyses of alongtrack altimetric wavenumber
68 spectra. How are these complex, f -variable zonal currents folded into alongtrack wavenumber
69 spectra, calculated in $10 \times 10^\circ$ bins with a dominant meridional sampling in the tropics? Also, the
70 tropics are characterized by strong ageostrophic flow, and the representativeness of geostrophic
71 balance from SSH to infer the tropical dynamics needs to be checked.

72
73 Another dynamical contribution that could flatten the SSH wavenumber spectra in the tropics is
74 associated with high-frequency processes. In altimetric SSH data, the high-frequency barotropic tides
75 are corrected using global barotropic tidal models, and in the tropics away from coasts and islands,
76 these barotropic tide corrections are quite accurate (Stammer et al., 2014). Altimetric data are also
77 corrected for the large-scale rapid barotropic response to high-frequency atmospheric forcing (< 20
78 days), the so-called Dynamical Atmospheric Correction, using a 2D barotropic model forced by high-
79 frequency winds and atmospheric pressure (Carrere and Lyard, 2003). With only 10 to 35-day repeat
80 sampling, altimetry cannot track the evolution of these rapid barotropic processes, and a correction
81 is applied to prevent aliasing of their energy into lower frequencies. In addition to these large-scale
82 barotropic corrections which are removed from the altimetric data, there exist high-frequency SSH
83 signals from internal tides and internal waves that contribute energy at small scales < 300 km
84 wavelengths. Their impact on SSH wavenumber spectra has been predicted from model analyses in
85 different regions (Richman et al., 2012, Ray and Zaron, 2016), and show that they can dominate in
86 regions of low eddy energy. Dufau et al. (2016) demonstrated that unsolved internal tides can
87 introduce spectral peaks in the altimetric wavenumber spectra from 100-300 km wavelength,
88 especially at low latitudes (Fig. 1b). Recent results from a high-resolution $1/48^\circ$ model highlight that
89 the tidal and supertidal signals in one region of the equatorial Pacific greatly exceed the subtidal
90 dynamics at scales less than 300 km wavelength, and supertidal phenomena are substantial at scales
91 approximately 100 km and smaller (Savage et al. 2017).

92 A more technical contribution that can impact on the lower spectral slopes in the tropics concerns

93 the altimetric data processing, the spectral calculation and spectral slope estimation. Much attention
94 has been devoted to the effects of altimetric noise (Xu and Fu, 2012; Zhou et al., 2015, Biri et al.,
95 2016) which can flatten the spectral slope calculation if the noise is not removed correctly. Different
96 studies also use different tapering windows to reduce leakage of non-periodic signals in limited-
97 length data series, which can also modify the spectral slope. In global studies, a fixed wavelength
98 band from 70-250 km is often used for the spectral slope calculation (Xu and Fu, 2012; Dufau et al.,
99 2016), which is appropriate for estimating the spectral slope of the energy cascade at mid-latitudes,
100 but may not be well-adapted for the tropics where the maximum spectral slope extends at longer
101 wavelengths, due to the larger Rossby radius there (Fig. 1b).

102
103 Thus, the interpretation of altimetric tropical SSH spectra, at spatial scales smaller than 600 km,
104 remains a matter of debate in terms of ocean dynamics. This paper aims at filling this gap by studying
105 the dynamical processes contributing to the small-scale SSH spectra in the tropical Pacific using
106 modeling and observational data. Two different approaches are proposed to better understand the
107 contributions to the observed altimetric flatter spectral slopes. Firstly, we wish to explore the
108 spectral signatures in SSH and EKE of the tropical Pacific mesoscale dynamics (with periods greater
109 than 10 days and wavelengths down to 25 km) and we will concentrate particularly on the tropical
110 “mesoscale” band that varies with latitude. For this, we analyse the global 1/12° DRACKAR model in
111 the tropical Pacific from 20°S to 20°N, using 5 day outputs covering the period 1987-2001. In
112 comparison to the altimetric analyses of Xu and Fu (2012) or Dufau et al. (2016), this model was
113 specifically chosen to have no high-frequency response to tides, internal waves or rapid tropical
114 waves, and is not limited at low wavelengths by the altimetric instrument noise, but rather by the
115 horizontal grid resolution. We will also use this model to explore the effects of using limited segment
116 lengths or specific windowing when calculating our wavenumber spectra.

117 In the second part of this paper, we will address the impact on SSH and EKE of the high-frequency
118 components using a unique modelling experiment: we will analyze a higher resolution and high-
119 frequency version of the model: a 1/36° regional model of the south west Pacific (Djath et al., 2014)
120 with and without tides. These two regional model runs have exactly the same configuration and high-
121 frequency atmospheric forcing, both versions include the atmospherically forced internal gravity
122 waves in the tropics. Careful filtering of the barotropic and coherent internal tides from the model
123 with tides also allows us to explore the relative impact of the incoherent tide-ocean circulation
124 interactions, and their signature on the alongtrack wavenumber spectra. This two-model
125 configuration allows us to make a brief investigation of the effects of high-frequency dynamics on the
126 wavenumber spectra, and to discuss the modeled spectra in comparison with altimetric wavenumber
127 spectra based on Topex/Poseidon, Jason and Saral/AltiKa altimeter data. These results will help to
128 better understand the physical content of altimetric observation today, as well as to explore the finer
129 scales that would be captured using future measurements of the SWOT satellite (Fu and Ubelmann,
130 2014).

131 In section 2, the different models and data used are presented. In section 3, we discuss processing
132 issues for the spectral calculation, particularly to reduce leakage effects in short tropical segments. In
133 section 4, we discuss the EKE spectral signature of the dynamics over the tropical Pacific as simulated
134 by the 1/12° resolution model. In section 5, results are discussed in term of balanced dynamics and
135 the 1/12° model’s SSH spectra are compared to Jason and Saral AltiKa wavenumber spectra. Finally,
136 the contribution of the high-frequency motions to the SSH spectral signature are investigated using

137 the 1/36° regional resolution model with and without tides, to illustrate its close match with
138 altimetric data. Section 6 presents the conclusions of our study.

139

140 **2 Models, and altimetric data**

141 **2.1 Models**

142 To study mesoscale and submesoscale activity from an OGCM, the model has to properly resolve the
143 corresponding dynamical scales (i.e., be eddy-resolving). The effective resolution for numerical
144 models is that 6-8 grid points are needed to properly resolve dynamical features (Soufflet et al.,
145 2016). In mid latitudes numerical convergence requires ~km horizontal resolution, however in the
146 tropics, because of the larger Ld due to the weaker Coriolis force, numerical convergence is obtained
147 from 1/12° horizontal resolution, and the increase of resolution to 1/36° only seems to displace the
148 dissipative range of the model toward smaller scale (Marchesiello et al., 2011).

149 In this paper, we first use a global model at 1/12° resolution from the DRAKKAR consortium based on
150 the NEMO code (Madec, 2008; Lecointre et al., 2011) referenced as G12d5. This model has 46 levels,
151 and has been integrated from 1989 to 2007 using a 3-hourly ERA-interim reanalysis (Dee et al., 2011).
152 The 3D velocities and the 2D Sea Surface Height (SSH) are saved as 5-day means during the period of
153 integration. This simulation has been used to document mesoscale variability in the South West
154 Pacific Solomon Sea (Gourdeau et al., 2014; Gourdeau et al., 2017). The present study will analyse
155 this simulation over the tropical Pacific between 20°N -20°S.

156 In the second part of the paper, we use a regional DRAKKAR/NEMO model with 1/36° resolution and
157 75 levels, still with surface forcing from the 3h ERA Interim re-analysis. Two simulations are
158 performed: one without tidal forcing (R36) over the 1992-2012 period, and one with tidal forcing
159 (R36T) over the 1992-2009 period (Tchilibou et al., 2018). These different model configurations are
160 particularly important in this area where internal tides are active (Niwa and Hibiwa, 2011; Gourdeau,
161 1998), and could modify accordingly the energy flux for the meso and submesoscale bands (Richman
162 et al., 2012). Daily mean model outputs are saved as (R36(T)d), as well as instantaneous fields saved
163 hourly (R36(T)h) during a 3 month period from January-March 1998. We will use these different
164 configurations to investigate the impact of high frequency ageostrophic motions such as baroclinic
165 tides and internal waves.

166 Further details on these different model configurations are given in Annexe 1.

167 **2.2 Altimetric data**

168 Along-track SSH observations from TOPEX/Poseidon covering a period (January 1993 to December
169 2001) in common with the G12d5 simulations are analyzed over the tropical Pacific domain. The
170 most recent altimetric missions (Jason-2 and SARAL/Altika) are also analyzed over the January-2013
171 to December-2014 period to compare with the signature of the high frequency modelled SSH in
172 R36Th. These data are made available from the Copernicus Marine and Environment Monitoring
173 Service (CMEMS, <http://marine.copernicus.eu>). TOPEX/Poseidon and Jason-2 are conventional pulse-
174 width limited altimeters operating in the Ku-band (Lambin et al., 2010). SARAL/Altika with its 40 Hz
175 Ka-band emitting frequency, its wider bandwidth, lower orbit, increased Pulse Repetitivity Frequency

176 and reduced antenna beamwidth, provides a smaller footprint and lower noise than the Ku-band
177 altimeters (Verron et al., 2015). For the different missions we will analyze the 1 Hz data, extracted
178 over the same region as our model analysis.

179

180 **3. Spectral methods**

181 In the following sections we present spectral analyses of the modelled SSH or EKE fields, or the
182 altimetric SSH. The spectral analysis we use is based on Fast Fourier Transforms (FFT) of our signal,
183 which allows us to work with a limited sampled signal. Longer data records enable a better
184 decomposition of the variability at each frequency (wavenumber) and thus a better separation of
185 neighboring frequencies in the spectrum. However, for wavenumber spectra, long spatial data
186 records can mix information from different geographical regimes, especially in the tropics where
187 meridional sections cross the strong zonal currents, making their dynamical interpretation difficult.
188

189 Different studies performing spectral analysis of altimetric data or models over the global ocean use
190 very different data length segments to calculate the spectrum. Some altimetric studies use data
191 segment lengths of around 500 km (e.g. Dufau et al., 2016), or 1000 km length tracks averaged in 10°
192 or 20° square box, with or without overlapping (Xu and Fu, 2012). Model spectra are mostly
193 calculated in 10° or 20° square boxes (e.g., Sasaki and Klein, 2012; Biri et al., 2016; Chassignet and Xu,
194 2017). These data segment lengths may be adequate for the mid-latitudes but are not appropriate
195 for the tropics, when the maximum energy can occur at 600-1000 km wavelengths. Using shorter
196 segments than this reduces the maximum energy and should increase the leakage from energetic low
197 wavenumbers to weaker high wavenumbers, thus decreasing the spectral slope (Bendat and Piersol,
198 2000).

199

200 A wide variety of filter windows are applied in the different studies before calculating frequency
201 (wavenumber) spectra to reduce the leakage effect. These include the 10 % cosine taper window or
202 Tukey 0.1 window, referred hereafter as Tk01 (LeTraon et al., 2008; Richman et al., 2012; Dufau et
203 al., 2016); the Hanning window, referred as Hann (Capet et al., 2008; Rocha et al., 2016); or making
204 the signal double periodic instead of the tapering, referred as Dbp (Marchesiello et al. 2011; Sasaki
205 and Klein, 2012; Chassignet and Xu, 2017). In the following, we will also consider a 50% cosine taper
206 window (Tk05).

207

208 We tested the sensitivity of our G12d5 model's SSH wavenumber spectrum to the different tapering
209 windows and the double periodic method, using different data length sizes, and in one or two
210 dimensions. The details are given in Annexe 2.

211 We find that to safely avoid leakage in the tropics, it is best to use a long record and an effective
212 taper window. The Tk05 or Hann filters give convincing results in the equatorial band, with a
213 minimum of 15° to 20° needed in segment lengths (Fig. A1). We do not advise to use the Tk01 filter
214 window. In the off-equator region, 10° data segments or 10°X10° boxes are sufficient. We choose to
215 use the Tukey 0.5 filter for our tropical spectral analyses in this paper.
216

217 **4 Spectral representation of the tropical dynamics**

218 In this section we analyze the spectral signatures of the tropical dynamics by first considering the
219 surface velocity fields of the G12d5 simulation over the open Pacific Ocean. Modeling studies mainly
220 analyze velocity or EKE fields, and we start our spectral analysis by checking that the model
221 represents well the main dynamical processes in the tropics. Surface velocity fields were averaged
222 over the first 40 m depth and include geostrophic and ageostrophic components. The model resolves
223 a domain of variability with periods greater than 10 days, and wavelengths exceeding 25 km, but
224 model dissipation may be active up to 70 km wavelength. Note that the resonant response to the
225 wind forcing through the 3-5 day period, large-scale equatorially trapped inertia-gravity waves, are
226 not represented in G12d5 because of the 5-day averaged model outputs.

227 The Tropical Pacific is characterized by a series of strong alternate zonal currents and a large range of
228 ocean variability, in response to the atmospheric forcing and to the intrinsic instability of the current
229 system. The main zonal currents spanning the tropical Pacific are shown in Fig. 2: North of 10°N is the
230 westward North Equatorial Current (NEC) and at its northern edge are the eastward SubTropical
231 CounterCurrent (STCC) and the Hawaiian Lee CounterCurrent (HLCC) (Kobashi and Kawamura, 2002;
232 Sasaki and Nonaka, 2006); between 3°-8°N is the eastward North Equatorial CounterCurrent (NECC);
233 South of 3°N, the westward South Equatorial Current (SEC) straddling the equator is divided in two
234 branches by the eastward Equatorial UnderCurrent (EUC) that reaches the surface to the east. The
235 eastward South Equatorial Counter Current (SECC) in the south western Pacific is between 6°-11°S.
236 Instabilities of these zonal currents result in meso and submesoscale activity illustrated by a snapshot
237 of vorticity (Fig. 2) that illustrates the description of vortices in Ubelmann and Fu (2011). It is
238 characterized by structures with a large range of scale and strong anisotropy in the equatorial band.
239 The largest structures (~500 km) correspond to the nonlinear Tropical Instability Vortices (TIVs), also
240 associated with the Tropical Instability Waves (TIWs), and occur north of the equator (Kennan and
241 Flament, 2000; Lyman et al., 2007). The off-equatorial regions (10-20° latitude) are characterized by
242 smaller-scale turbulent structures in Fig. 2.

243 In order to investigate how these well-known tropical dynamics project into frequency or
244 wavenumber spectra, we will analyze separately the equatorial band (10°S-10°N) and the off-
245 equatorial band (10°N-20°N and 10°S-20°S) defined by the different boxes in Fig. 2. The model's
246 representation of the following diagnostics will be discussed together for each zonal band : the EKE
247 frequency spectra as a function of latitude and longitude (Fig. 3), the zonal EKE wavenumber-
248 frequency (k - ω) spectra and meridional EKE wavenumber-frequency (l - ω) spectra (Fig. 4), and the 1D
249 (zonal/meridional) EKE wavenumber spectra (Fig. 5).

250 251 **4.1 Equatorial region**

252 The temporal variability of the tropical EKE signal is shown by EKE frequency spectra as a function of
253 latitude and longitude in Fig. 3. In the equatorial band, most of the energy is concentrated within 5°
254 of the equator (Fig. 3a). The highest EKE occurs in this band at annual to interannual scales, but there
255 is still significant energy over all frequencies greater than the 10-days resolved by this model. EKE
256 spectra averaged in latitude over 20°N-20°S are highly influenced by the energetic equatorial
257 dynamics (Fig. 3b). This band includes the equatorial wave guide where waves tend to propagate
258 zonally and are organized into a set of discrete meridional modes (Farrar, 2008). Since zonal
259 wavenumber-frequency spectra are averaged from a number of latitudes within the equatorial band,

260 contributions from the different modes may be seen at once (Fig. 4b). The eastward phase speed
261 (positive wavenumber), due to fast moving Kelvin waves at the equator is visible even if the strong
262 westward propagation (negative wavenumber) just off the equator overpowers the eastward
263 propagation on the equator in the averaged spectrum. We have superimposed on the zonal
264 wavenumber-frequency spectrum the theoretical dispersion curves of the first baroclinic-Rossby
265 waves in a resting ocean. Values of wavenumber and frequency for which the EKE power spectrum is
266 significantly above the background follow relatively well the variance-weighted mean location of
267 dispersion curves for long equatorial waves. Meridional wavenumber-frequency (l - ω) EKE spectra
268 were computed over the 20°N to 20°S section, in different longitude bands spanning the Pacific
269 Ocean. Figure 4d shows an example for the particularly energetic 120°W-150°W band. Other
270 longitude bands across the Pacific show similar spectral energy patterns, but with lower energy
271 levels. Figures 4b,d illustrate the strong anisotropy between the zonal (k , ω) and meridional (l , ω)
272 spectra. The meridional structure of the dominant zonal equatorial waves is well known, with
273 meridional amplitude decaying away from the equator over $\pm 5^\circ$ or 550 km. This contributes in the
274 meridional-frequency EKE spectrum to the fairly constant decrease in spectral energy from long
275 wavelengths down to 100-250 km wavelength, in both north and south directions (Fig. 4d).

276
277 The ridge of westward variance (Fig. 4b) is nearly vertical, with variance mainly restricted to large
278 wavelengths but also extending to high frequencies in relation with TIW activity. In accordance with
279 observations (Willett, 2006; Lee et al. 2018), the modeled TIWs are defined by periods and zonal
280 wavelengths in the range of 15-40 days and 800-2000 km, respectively. They have a meridional
281 propagation with northward and southward motions roughly balanced that is a hallmark of standing
282 meridional modes for TIWs as seen in Lyman et al. (2005) and Farrar (2008, 2011) and earlier work
283 (Fig. 4d). The 33-day TIW variability is triggered by baroclinic instability of the SEC-NECC system,
284 located between 3°N-5°N and 160°W-120°W (Fig. 3a,b). They have an asymmetric structure across
285 the equator with larger energy north of the equator than south of it in accordance with the analysis
286 of TOPEX/Poseidon sea level data by Farrar (2008). The 20-25 days variability, associated with
287 another type of TIW triggers by barotropic instability of the EUC-SEC system (Masina et al., 1999), is
288 centered at the equator, east of 140°W (Fig. 3a,b). Centered at the equator, from the background
289 there is a 60-80 days variability extending from 150°E to 130°W (Fig. 3a,b) associated with
290 intraseasonal Kelvin waves (Cravatte et al., 2003; Kessler et al., 1995) as confirmed by eastward
291 variance and energy centered at $l=0$ in the zonal and meridional-frequency spectra, respectively (Fig.
292 4b,d).

293
294 The model represents these tropical signals well, and for wavelengths larger than 600 km the
295 equatorial waves are the dominant signal (Tulloch et al., 2009). For wavelengths smaller than 600
296 km, the variance no longer follows the Rossby wave dispersion curves, and exhibits a red noise
297 character in wavelength, and a nearly white noise in frequency. These rapid motions with 250-600
298 km wavelengths occur in response to wind forcing, wave interactions or current instability. The
299 corresponding zonal EKE wavenumber spectrum (Fig. 5) has a steep slope that continues rising to
300 long wavelengths with a k^{-3} relation reaching a peak at 1000 km, reflecting the zonal scales of the
301 TIWs, before flattening to a k^{-1} power law at larger scale. Below 70 km, EKE spectra drastically
302 steepen as an effect of model dissipation.

303 **4.2 Off equatorial regions**

304 Poleward of 10° the equatorial trapped waves become insignificant, and most of the energy is
305 concentrated at periods greater than 60 days (Fig. 3a). This corresponds with results by Fu (2004)
306 showing a decreasing frequency range with latitude, where the maximum frequency at each latitude
307 corresponds to the critical frequency of the first-mode baroclinic waves that varies from 60 days at
308 10°S to 110 days at 20°S (Lin et al., 2008). The zonal wavenumber-frequency spectrum strongly
309 differs from those in the equatorial belt (Fig. 4a,c), and is closer to the mid latitude spectra (Wunsch,
310 2010; Wakata, 2007; Fu, 2004) with smaller energy in the south tropics than in the north as also
311 reported by Fu (2004). The theoretical dispersion curves for mid latitude first baroclinic Rossby waves
312 are shown for the case of meridional wavenumbers corresponding to infinite wavelengths. At low
313 wavenumbers (i.e., long wavelengths > 600 km) the motions follow the baroclinic dispersion curves.

314 Although linear Rossby wave theory provides a first - order description of the EKE spectra, in both
315 hemispheres energy extends to higher frequencies (Fig. 3a), and as the wavenumber and frequency
316 increases, significant deviations from the baroclinic dispersion curves occur (Fig. 4a,c). Much of the
317 energy lies approximately along a straight line called the ‘non dispersive line’ in wavenumber-
318 frequency space as it implies non-dispersive motions. The wavenumber dependencies along the ‘non
319 dispersive line’ could be the signature of non-linear eddies (Rhines, 1975). The westward propagation
320 speed is estimated at ≈ 10 cm/s, close to the eddy propagation speed found in this latitudinal range
321 by Fu (2009) and Chelton et al. (2007). But these regions are defined as a weakly nonlinear regime
322 (Klocker and Abernathy, 2014). In this region of mean zonal currents the dispersion curves
323 experience Doppler shifting by the zonal flow which makes the variability nearly non dispersive
324 (Farrar and Weller, 2006). So, the non-dispersive line could account for coherent vortices and more
325 linear dynamics as Rossby waves or meandering jets propagating westward (Mortén et al., 2017).

326 The zonal EKE wavenumber spectra (Fig. 5) in the off equatorial regions exhibit a standard shape with
327 a long-wavelength plateau and a spectral break at about 300-400 km, following by a drop in energy
328 close to a k^2/k^3 relation (Stammer, 1997). These steep spectral slopes correspond with an inertial
329 range characteristic of mesoscale turbulence (Xu and Fu, 2011). These different spectra confirm that
330 the northern tropics are more energetic than the southern part with a mesoscale range extending to
331 larger scale. It quantifies the more active turbulence in the northern hemisphere, as illustrated in Fig.
332 2.

333 **4.3 Anisotropic EKE spectra**

334
335 Classically, wavenumber spectra are investigated throughout an oceanic basin by dividing the basin
336 in square boxes where spectra are calculated to take account of the regional diversity of QG
337 turbulence properties (Xu and Fu, 2011; Sasaki and Klein, 2012; Biri et al., 2016; Dufau et al., 2016).
338 Here, the spectra analysis of the equatorial and off-equatorial bands described above is revisited in
339 $10^\circ \times 10^\circ$ boxes for the off-equatorial region, and in $20^\circ \times 20^\circ$ boxes for the equatorial region that are
340 suited to recover the shape of the mesoscale range in the tropics (e.g. section 3). Within each
341 equatorial or off equatorial latitude band, spectra in the different boxes are similar (not shown).
342 Therefore spectra are averaged over all the boxes and we present one mean spectrum
343 representative of the square boxes for each equatorial, and off equatorial bands. In geostrophic
344 turbulence, which is nondivergent to leading-order, isotropy implies that 1D (zonal/meridional) and
345 2D azimuthally integrated wavenumber spectra (or wavenumber magnitude spectra), are identical
346 and follow the same power law. In the tropics there is a stronger anisotropic component of the

347 dynamics, which will be explored in Fig. 6.

348
349 When we concentrate on the 20°x20° equatorial box, we are limited to wavelengths smaller than
350 2000 km, and the meridional EKE spectrum has a higher level of energy than the zonal one (Fig. 6b).
351 This reflects a shift of energy towards the smaller scales in the meridional direction that is consistent
352 with the widely held notion that scales of variability near the equator tend to be larger in the zonal
353 direction than in the meridional direction for many kinds of variability (mean currents, inertia-gravity
354 waves, Kelvin waves, Yanai waves, TIWs). The magnitude EKE spectrum is mostly representative of
355 the meridional one. Note that since alongtrack altimetry is mainly orientated in the meridional
356 direction in the tropics, altimetric SSH measurements are particularly well suited to account for the
357 dominant meridional variability, within the limit of the geostrophic hypothesis. Despite the
358 anisotropy at every scale, the different EKE spectral components have a similar shape, with a
359 continuous k^{-3} slope between 100 and 600 km wavelength. The peak of the EKE spectra corresponds
360 to a wavelength of 1000 km. These modeling results compare relatively well with the analysis of the
361 submesoscale dynamics associated with the TIWs by Marchesiello et al. (2011). They observe a peak
362 of energy around 1000 km corresponding to the TIW wavelength, and a linearly decay of the
363 spectrum with a slope shallower than -3. It is doubtful to define an inertial band in the equatorial
364 region, but we can say that at wavelengths from 100-600 km, the EKE spectral slope of k^{-3} is
365 consistent with a QG cascade of turbulence.

366
367 In the 10°x10° off-equatorial boxes, the energy at long wavelengths is greatly reduced compared to
368 the equatorial band. The peak of the EKE spectra corresponds to a wavelength of 300 km. Yet the
369 zonal, meridional and magnitude EKE spectra are similar for wavelengths up to 250 km (Fig. 6a,c). So,
370 poleward of 10° the hypothesis of isotropy seems to be relevant for scales up to 250 km even if the
371 flow is supposed to be weakly nonlinear, and sensitive to beta effect (Klocker and Abernathey, 2014).
372 The EKE slope over the redefined mesoscale range from 100 to 250 km is between -2 and -3 which
373 lies between the prediction of SQG and QG turbulence.

374
375 Our modeled zonal frequency-wavenumber spectra differ strongly across the equatorial and off
376 equatorial regions. They show a good representation of the tropical wave and TIW/TIV dynamics. The
377 slope of the ridge of westward variance in the zonal k - ω spectrum in Fig. 4 increases towards the
378 equator. As the slope becomes steeper, more power is concentrated at lower wavenumbers. The
379 change in slope of the ridge itself is mainly related to the change in deformation radius, and
380 expresses linear or non-linear variability propagating non dispersively (Wortham and Wunsch, 2014).
381 The equatorial region differs from the off equatorial regions in having strong anisotropy with mainly
382 zonally oriented structures (Fig. 6), higher energy at long wavelength due to the strong activity of
383 long equatorial waves, and an overlap between geostrophic turbulence and Rossby wave time scales
384 that produces long waves and slows down the energy cascade to eddies with scales consistent in the
385 tropics with a generalized Rhines scale (L_r) (Theiss, 2004, Tulloch et al., 2009; Klocker et al., 2016;
386 Eden, 2007). Moreover, our modeled spectral analysis shows the contrasts between the equatorial
387 and off-equatorial regions for the wavenumber range where a steep slope is observed. In the weakly
388 nonlinear regime of the off-equatorial regions, we find spectral slopes of k^{-2} / k^{-3} over a short 100-250
389 km wavenumber range. The equatorial dynamics are characterized by a peak of energy at 1000 km
390 due to TIWs, and a large “mesoscale” range over 100-600 km wavelength with a k^{-3} spectral slope.

391

392 **5 Modeled and altimetric SSH wavenumber spectra**

393 **5.1 Contribution from low-frequency dynamics**

394 The SSH is a measure of the surface pressure field, an important dynamical variable, which may be
395 balanced in the tropics by both geostrophic and ageostrophic motions. The ocean circulation is
396 classically inferred from altimetric SSH through the geostrophic equilibrium. Here, we consider how
397 the wavenumber spectra of geostrophic currents (EKEg) differ from that of the total currents
398 analyzed in section 4. Close to the equator, as f approaches zero, the geostrophic current component
399 can still be calculated using the beta approximation, following Picaut et al. (1989). Figure 6 shows the
400 difference between the wavenumber spectra calculated from the total EKE averaged over the upper
401 40 m, and from the geostrophic component of EKE estimated at the surface.

402 In the equatorial band at scales from 300 to 1000 km, the ageostrophic EKE is more energetic, with a
403 stronger contribution to the total EKE than the geostrophic component (Fig. 6b). In the off-equatorial
404 bands (Fig. 6a,c), the geostrophic and total EKE spectra are similar at larger wavelengths. However, in
405 all regions, the total EKE is steeper than the geostrophic EKE at scales from 250 km down to the 20
406 km resolved by the model. In mid latitude regions, Ponte et al. (2013) also noted stronger
407 geostrophic EKE at small wavelengths (and weaker spectral slopes) compared to upper ocean EKE
408 spectra, associated with wind-driven mixed layer dynamics. In terms of spectral slope in the
409 equatorial region, using the geostrophic EKE rather than the total EKE tends to flatten the spectra in
410 the 600-110 km mesoscale range, and changes the spectral slope from k^3 to k^2 . In the off-equatorial
411 regions, the geostrophic EKE has a slightly flatter spectral slope between -2 and -3 in the 100-250 km
412 band.

413

414 Since the altimetric groundtracks have a more meridional orientation in the tropics, the altimetric
415 SSH spectra should be like the model's meridional SSH spectra that are shown on Figure 7. SSH
416 meridional wavenumber spectra (Fig. 7) confirm that in the off-equatorial regions, the northern zone
417 has higher spectral power over all wavelengths, as expected from the EKEg spectra. Within the
418 wavelength band from 100 to 250 km both off-equatorial regions have SSH spectral slopes between
419 k^4 to k^5 (equivalent to k^2/k^3 in EKE) similar to QG dynamics. The modelled SSH spectra show a
420 similar anisotropy in the equatorial zone as the EKE spectra, with a more energetic meridional SSH
421 spectrum than the zonal spectrum (not shown). It is notable that although the level of energy is
422 higher in the equatorial region than in the off-equatorial regions, the SSH variability is lower for
423 wavelengths smaller than 500 km. This reduced SSH variability of the G12d5 model is not in
424 agreement with the higher small "scale" SSH levels altimetry to be discussed in the next section
425 (section 5.2). From 100 to 600 km, the SSH spectral slopes in the equatorial region are close to k^4 ,
426 consistent with the k^2 spectral slopes in EKEg. The fixed wavelength band used by previous studies
427 [70-250 km] can be compared to this longer wavelength band. Using the fixed wavelength band leads
428 to a slight reduction in the low-frequency SSH spectral slope estimate, but without a drastic
429 modification. These results indicate that if the internal balanced dynamics of our $1/12^\circ$ model were
430 the main contribution to the altimetric SSH, then we would expect a k^4 (sQG) slope in the equatorial
431 band, and closer to k^5 (QG) in the off-equatorial band.

432 Fig. 7 also shows the alongtrack Topex/Poseidon SSH spectra over the same region and period as the
433 G12d5 simulation. The altimetric data are selected with the same segment lengths, and with the
434 same pre-processing and spectral filtering as in the model. In the equatorial and off-equatorial zones,
435 the altimetric SSH wavenumber spectra clearly exhibit the weaker k^2/k^{-1} spectral slopes in the 70-250
436 km mesoscale range as described in previous studies (Xu and Fu, 2011, 2012; Zhou et al., 2015). At
437 scales larger than our spectral slope range (600 km in the equatorial region, 200 km in the off-
438 equatorial zones), the model-altimeter spectra have similar shapes although the altimeter data has
439 higher spectral power. Potentially, the high-frequency $< 10d$ rapid equatorial waves, with longer
440 wavelengths not included in the model, may contribute to these differences. The spectral peaks in
441 the altimetric data at 120-150 km wavelength are indicative of internal tides, as noted by Dufau et al.
442 (2016), Savage et al., (2017), and others. In addition to the internal tide peaks, the general higher
443 spectral energy in the altimetry data at wavelengths < 200 km has been proposed to be due to high-
444 frequency internal gravity waves (eg Richman et al., 2012, Savage et al., 2017), but may also include
445 altimetric errors from surface waves and instrument noise (Dibarboure et al., 2014). We will
446 investigate the high-frequency contribution to the altimetric SSH spectra in the next section.

447 **5.2 Contributions from high-frequency dynamics including internal tides**

448 To investigate the contribution of the high-frequency SSH variations, we include an analysis of the
449 meridional SSH spectra from a small region east of the Solomon Sea in the South West Pacific. This
450 spectral analysis is derived from the $1/36^\circ$ model with high-frequency atmospheric forcing and
451 instantaneous snapshots saved once per hour during a 3 month period, and run in the two
452 configurations, with and without tides (see section 2). The model has been validated and analysed
453 (Djath et al., 2014), and a companion paper will address the model with tides more fully (Tchilibou et
454 al., 2018). Here we consider specifically the impact of the different high-frequency tides and non-
455 tidal signals on the meridional SSH spectra.

456 The internal tide can be broken down into a coherent component that is predictable and can be
457 separated with harmonic and modal analysis, and an incoherent component that varies over time,
458 due to changing stratification (Zaron, 2017) or interaction with the mesoscale ocean circulation
459 (Ponte and Klein, 2015). The coherent baroclinic (internal) tide and the barotropic tide are calculated
460 in our study using a harmonic and modal decomposition (Nugroho, 2017) which separates the
461 barotropic mode and 9 internal tide modes, and provides a more stable energy repartition between
462 the baroclinic and barotropic components (F. Lyard, Personal Communication). Previous studies have
463 addressed the internal tide and high-frequency components in the tropics by careful filtering of a
464 model with tides (e.g. Richman et al., 2012; Savage et al., 2017). Aside from the issues of artifacts
465 introduced by the tidal filtering, it is often tricky to cleanly separate the spectral contributions
466 coming from the mesoscale ocean circulation and the incoherent component of the internal tides.
467 The advantage of using our two-model configuration is that we can specifically calculate the high-
468 frequency non-tidal components of the SSH spectra from the first model, and the component due to
469 the interaction of the internal tide and the model's eddy-current turbulence with the second model.

470 Figure 8 shows the geographical distribution of the standard deviation of SSH for the model including
471 the tidal forcing for the low frequency (> 48 hr) component of the ocean (mesoscale) dynamics and
472 for the high frequency component (< 48 hr) due mainly to internal waves and internal tides. The large
473 mesoscale variability (up to 6 cm) east of the Solomon Sea in Fig. 8a is similar to the model without

474 tides (not shown), and well documented as current instability from the SECC-SEC current system (Qiu
475 and Chen, 2004). It is notable that the high frequency variability from the model with tides in Fig. 8b
476 is as high as the mesoscale variability, especially in the Solomon Sea, and comes mainly from the M2
477 baroclinic tide. We note that the M2 barotropic tide amplitude within the Solomon Sea is relatively
478 weak (not shown), and the largest internal tide amplitudes are close to their generation sites,
479 particularly where the barotropic tide interacts with the northern and southern Solomon Islands and
480 the southeastern Papua New Guinea (PNG) extremities (Tchilibou et al., 2018). For the model
481 without tides, the high frequency variability due to the atmospherically forced internal gravity waves
482 is very low (~ 1 cm) compared to the model with tides, and shows a relatively uniform distribution
483 (not shown).

484 The region used for our spectral analysis [2-13°S; 163-165°E; Fig. 8b] is outside the Solomon Sea with
485 its strong regional circulation delimited by the islands and bathymetric gradients, and is more
486 representative of the open Pacific Ocean conditions analysed in the previous sections. The latitude
487 band from 2°S-13°S lies mostly the equatorial band defined in our previous analyses, and it is mainly
488 representative of the SECC region (Fig. 2).

489 The meridional SSH spectra from the $1/36^\circ$ model run with no tides (R36h) with hourly outputs is
490 shown in Fig. 9 (in green). The SSH from this version with no tides but averaged over 5 days is also
491 shown (in orange), i.e., with equivalent temporal sampling to our $1/12^\circ$ model analysis. The
492 difference between these curves represents the non-tidal high-frequency component of the
493 circulation (< 10 days) due to rapid tropical waves and internal gravity waves forced by the
494 atmospheric forcing and current-bathymetric interactions. Also shown is the spectrum calculated at
495 the same location from our open-ocean G12d5 $1/12^\circ$ model (in cyan) with similar spectral slope to
496 the 5-day averaged version of our regional R36h $1/36^\circ$ model, though with slightly lower energy at
497 scales less than 70 km wavelength as expected, but also in the 180 to 600 km wavelength band. So
498 the $1/36^\circ$ model with no tides, when filtered to remove the high-frequency forcing, is quite close to
499 the $1/12^\circ$ model in this equatorial band. The main point is that the additional high-frequency
500 dynamics in R36h increase the spectral SSH power from 300 km down to the smallest scales from 0.4
501 cm^2 to 0.5 cm^2 , and reduce the spectral slope calculated in the fixed 70-250 km range from k^{-5} with
502 the 5-day average (in orange), to k^{-4} for the full model with no tides (in green).

503 The $1/36^\circ$ model with tides (R36Th) is also shown in blue, but with the barotropic tide removed. The
504 additional meridional SSH spectral power is due both to the coherent and incoherent internal tides,
505 with a large increase in variance up to 300 km wavelength from 0.5 cm^2 for R36h to 2.8 cm^2 for
506 R36Th. So, the main contributors to the high wavenumber SSH spectral power are from the baroclinic
507 tides compared to atmospherically-forced high frequency dynamics (green curve). To illustrate the
508 respective part of coherent and incoherent baroclinic tides, the coherent baroclinic tide signature
509 based on the nine tidal constituents summed over the first 9 internal modes is calculated, and this
510 signal is added to the model without tides (purple curve). The coherent baroclinic tides explain most
511 of the tidal signature in the 300-30 km wavelength range, and the difference with the raw signal
512 (blue curve) exhibits the signature of incoherent tides. The contribution of the incoherent
513 component increases significantly at scales smaller than 30 km and explain 30 % of the SSH variance.
514 The most energetic coherent internal tide component comes from the M2 tide, and the large
515 increase in amplitude centered around 120-140 km wavelength corresponds with the first baroclinic
516 mode (not shown). The other peaks around 70 km, and 40 km could be due to higher modes, and

517 similar peaks are found in the tidal analysis of MITGCM model data by Savage et al (2017) in the
518 central equatorial Pacific. At the main M2 internal tide wavelengths, the incoherent internal tide has
519 1.6 times the SSH energy of the coherent tide, indicating that even at the main internal tide
520 wavelengths, the incoherent internal tide is energetic.

521 We note that at wavelengths from 70-250 km used in the global altimetry spectral analysis, this 1/36°
522 model with the full tidal and high-frequency forcing has a flat spectral slope of around $k^{-1.5}$, quite
523 similar to the analysis of alongtrack spectral from Jason-2 (in dashed black) and Saral (in solid black),
524 in the same region but over the longer 2013-2014 period. We note that the barotropic tide has also
525 been removed from the altimetric data, using the same global tide atlas applied at the open
526 boundary conditions for our regional model (FES2014, Lyard et al., 2018). If we use the “mesoscale”
527 range defined for the global model analysis in the equatorial band over 100-600 km wavelength, we
528 still have a weak spectral slope of k^{-2} for both the model with tides and altimetry. Jason-2 has a
529 higher noise level than Saral at scales less than 30 km wavelength (Dufau et al., 2016); the small
530 differences in spectral energy between Jason-2 and Saral over wavelengths from 150 to 450 km may
531 be influenced by the different repetitive cycles of the very few tracks available (1 track for Jason-2
532 and 3 tracks for SARAL/AltiKA) between both missions, and their slightly different track positions.

533 This regional analysis provides a number of key results. The high-frequency, high-resolution regional
534 model confirms our open ocean 1/12° analysis. The dynamics at scales > 10 days, with no tidal
535 forcing, give rise to SSH spectral slopes from 70-250 km of around k^{-5} in this equatorial band in
536 accordance with the G12d5 simulation. Note that it differs from the k^{-4} slope typical of the equatorial
537 region discussed above. It reflects modulation associated with low frequency variability. This 3 month
538 period corresponds with an El Niño event characterized by relatively low mesoscale activity in this
539 region of the South West Pacific (Gourdeau et al., 2014). Including the high-frequency but non-tidal
540 forcing increases the smaller-scale energy, and flattens the SSH spectra with slopes of around k^{-4} . This
541 non-tidal high-frequency (< 10 -day) component increases the SSH spectral energy out to scales of
542 200 km wavelength, suggesting a dominance of rapid small-scale variability of internal gravity waves
543 (Garrett and Munk, 1975). But the higher frequency atmospheric forcing and ocean instabilities alone
544 cannot explain the very flat altimetric spectral slopes in this equatorial region.

545 When coherent and incoherent internal tides are included, the spectral slope in the 70-250 km
546 wavelength band becomes very close to that observed with altimetric spectra. This confirms the
547 recent results presented by Savage et al. (2017) for a small box in the eastern tropics, and previously
548 proposed by Richman et al. (2012) and Dufau et al. (2016). The separation of the coherent M2
549 internal tide demonstrates that it clearly contributes SSH energy in the 50-300 km wavelength band,
550 but the incoherent tide, and its cascade of energy into the supertidal frequencies, is the dominant
551 signal at scales less than 50 km. The incoherent and coherent internal tides have similar energy
552 partitioning within the 50-300 km wavelength band.

553

554 **6. Discussion and Conclusion**

555

556 The processes that could contribute to the flat Sea Surface Height (SSH) wavenumber spectral slopes
557 observed in the tropics by satellite altimetry have been examined in the tropical Pacific. This study
558 has used two complementary approaches to better understand how the equatorial and off-

559 equatorial dynamics impact on the SSH wavenumber spectra. In the first part of this study, we have
560 concentrated on the low-frequency (> 10 days) tropical dynamics to better understand how the
561 complex zonal current system and dominant linear tropical waves affect the mainly meridional
562 altimetric SSH wavenumber spectra. In the second part of the study, we have used a high-frequency,
563 high-resolution regional modeling configuration, with and without tides, to explore the high-
564 frequency contributions to the meridional SSH wavenumber spectra.

565 Our $1/12^\circ$, 5-day averaged model confirms the results from previous modeling studies that at
566 seasonal to interannual time scales the most energetic large-scale structures tend to be anisotropic
567 and governed by linear dynamics. At intraseasonal frequencies and in the tropical “mesoscale” band
568 at scales less than 600 km wavelength, one major question was how the cascade of energy is affected
569 by the expected high level of anisotropy and the weak non-linear regimes. Within the “mesoscale”
570 range, the EKE wavenumber spectra are isotropic in the off-equatorial regions between 10° and 20° ,
571 and it is more anisotropic in the equatorial region between 10°N - 10°S , with higher level of energy for
572 the meridional EKE spectrum than for the zonal one that reveals larger scales of variability in the
573 zonal direction than in the meridional direction, as expected. In the off-equatorial range, EKE peaks
574 at around 300 km wavelength, and the steep EKE decrease at smaller wavelength is characterized by
575 spectral slopes between k^{-2} and k^{-3} , which lie between the regimes of SQG and QG turbulence. These
576 weakly nonlinear off-equatorial regions thus have a similar structure to the non-linear mid-latitudes
577 within the range from 100-250 km. In the equatorial band from 10°S - 10°N , the total EKE is more
578 energetic than the off-equatorial region, and the EKE spectral slope approaches k^{-3} over a large
579 wavenumber range, from 100 to 600 km, consistent with QG dynamics, even though there is a strong
580 ageostrophic component here. Using the fixed wavelength (70-250 km) band to estimate
581 “mesoscale” spectral slope leads to a slight reduction in the low-frequency spectral slope estimate,
582 but without a drastic modification. When geostrophic velocities are used to calculate EKE rather than
583 the total surface flow, there is similar spectral energy in the off-equatorial regions at longer
584 wavelengths. In the equatorial band 10°N - 10°S , the ageostrophy is more evident with a more marked
585 change in spectral slope based on geostrophic velocities and the beta-approximation at the equator.
586 At large scales in the equatorial band, the ageostrophic equatorial currents are more active, related
587 to the energetic zonal currents. In all regions, at wavelengths shorter than 200 km, the geostrophic
588 spectra become more energetic and the small-scale ageostrophic components are counteracting the
589 balanced geostrophic flow, as found at mid-latitudes (Klein et al., 2008; Ponte et al., 2015). This gives
590 a slightly flatter spectral slope over the 70-250 km wavelength, but the regime remains between k^{-2}
591 and k^{-3} in the off-equatorial region, approaching k^{-2} (and k^{-4} in SSH) in the equatorial band. So using
592 SSH and geostrophic currents slightly flattens the EKE wavenumber spectra, but the modeled SSH
593 wavenumber spectra maintain a steep slope that doesn’t match the observed altimetric SSH spectra.

594 The choice of regional box size and filtering options also impacts on the spectra. Previous global
595 altimetric studies have calculated alongtrack SSH wavenumber spectra in $10\times 10^\circ$ boxes, and with
596 varying segment lengths (512 km for Dufau et al., 2016; around 1000 km for Xu and Fu, 2011,
597 Chassignet et al., 2017, etc), and with different tapering or filtering applied (see section 3). In the
598 equatorial band where the EKE peak extends out to 600 km wavelength, it is important to have
599 segment sizes and filtering that preserve this peak and shorter scales. The combined effects of a 10%
600 cosine taper and the short segment lengths leads to a much flatter altimetric SSH spectra, reaching k^{-1}
601 in the Dufau et al (2016) study. We find that the double periodic spectra, the hanning and tukey
602 50% taper filter all give similar results in the tropics, but it is necessary to extend the box size to a

603 minimum of 15° to 20° in segment length or box size in the equatorial band. In the off-equatorial
604 band, these filtering options with a 10° segment length or box size are sufficient. Even with the
605 preferred pre-processing for the altimetric data, and larger segment lengths in our analyses, the
606 altimetric SSH spectra remain quite flat (k^{-2} in the off-equatorial zone, $k^{-1.3}$ in the equatorial band),
607 and do not reflect the steeper spectral slopes predicted by the model.

608 The regional high-resolution models with both high-frequency atmospheric and tidal forcing and
609 high-frequency hourly outputs provide the last pieces of the puzzle. In contrast to previous results
610 based on global ocean models with tidal forcing (Richman et al., 2012; Savage et al., 2017), this 2-
611 model configuration with and without tides, has the same atmospheric and boundary forcing, which
612 allows us to clearly separate the internal tide signals from the high frequency dynamical component.
613 Even though only a small region of the tropical Pacific is available for this analysis, the regional model
614 and the global 1/12° model show similar QG spectral slopes when they are compared over the same
615 domain and with 5-day averaged data. Using hourly data and no tides increases the SSH spectral
616 power at scales smaller than 200 km, possibly due to internal gravity waves in the tropics (Farrar and
617 Durland, 2012; Garrett and Munk, 1975). We note that Rocha et al. (2016) found a similar increase in
618 their detided alongtrack model runs in Drake Passage, but at scales less than 40 km wavelength, far
619 below the noise level of our present altimeter constellation. In the tropics, this contribution of high-
620 frequency non-tidal SSH signals out to 200 km wavelength will also impact on today's alongtrack
621 altimeter constellation, whose noise levels block ocean signals at scales less than 70 km for Jason
622 class satellites, and 30-50 km for Saral and Sentinel-3 SAR altimeters (Dufau et al., 2016). So non-tidal
623 internal gravity waves will partially contribute to the higher small-scale SSH variance and flatter
624 spectral slopes in today's altimetric SSH data.

625 The regional model with tides shows the very important contribution of internal tides to the flat SSH
626 slopes in the tropics. We have separated out the predictive part of the barotropic tide and internal
627 tides, since open ocean barotropic tides are well corrected for in altimetric data today (Lyard et al.,
628 2018; Stammer et al., 2014), and corrections are becoming available for the coherent part of the
629 internal tide (Ray and Zaron, 2016). In this open ocean tropical region east of the Solomon Sea, when
630 coherent and incoherent internal tides are included, the spectral slope in the 70-250 km wavelength
631 band becomes very close to that observed with altimetric spectra. This confirms the recent results
632 presented by Savage et al. (2017) for a small box in the eastern tropics, and previously proposed by
633 Richman et al. (2012) and Dufau et al. (2016). The separation of the coherent M2 internal tide
634 demonstrates that it clearly contributes significant SSH energy in the 50-300 km wavelength band,
635 but around the main internal tide wavelengths, there is a strong signature of M2 incoherent internal
636 tide. The incoherent tide, and its cascade of energy into the supertidal frequencies, is the dominant
637 signal at scales less than 50 km. This strong incoherent internal tide is consistent with recent studies
638 that suggest that internal tides interacting with energetic zonal jets can generate a major incoherent
639 internal tide (Ponte and Klein, 2015), and may explain the reduction of the coherent internal tides in
640 the equatorial band in global models (Shriver et al., 2014) and altimetric analyses (Ray and Zaron,
641 2016). Our model highlights that the internal tide signal is strong in this equatorial region, and the
642 incoherent tide accounts for 35% of the SSH spectral power in the 50-300 km wavelength band, and
643 is not predictable.

644 These results have important consequences for the analyses of alongtrack altimetric data today, and
645 for the future high-resolution swath missions such as SWOT. Today's constellation of satellite

646 altimeters have their alongtrack data filtered to remove noise at scales less than 70 km for all
647 missions (Dibarboure et al., 2014; Dufau et al., 2016), and these data are now being used with no
648 internal tide correction in the global gridded altimetry maps of SSH and geostrophic currents. The
649 imprint of these internal tides is evident in the alongtrack data (see Fig. 1b from Dufau et al., 2016)
650 but is also present in the gridded maps (R. Ray, personal communication). In the future, a coherent
651 internal tide correction may be applied to the alongtrack data based on Ray and Zaron (2016), to
652 reduce some of this non-balanced signal. It is particularly important to remove the unbalanced
653 internal wave signals from SSH before calculating geostrophic currents. But it is clear that the
654 incoherent internal tide and internal gravity waves reach scales of 200 km in the tropics, and their
655 signature in SSH remains a big issue for detecting balanced internal ocean currents from alongtrack
656 altimetry and the future SWOT wide-swath altimeter mission. Removing this signal to detect purely
657 balanced motions will be challenging, since filtering over 200 km removes much of the small-scale
658 ocean dynamics of interest in the tropics. On the other hand, there will also be a great opportunity to
659 investigate the interaction of the internal tide and ocean dynamics in the tropics in the future, with
660 both models and fine-scale altimetric observations.

661

662 **Acknowledgments**

663 The authors wish to acknowledge Ssalto/Duacs AVISO who produced the altimeter products, with
664 support from CNES (<http://www.aviso.altimetry.fr/duacs/>). The authors would like to thank the
665 DRAKKAR team for providing them with the high resolution global ocean simulation, and especially
666 J.M. Molines for his support. This work benefited from discussions with J. Jouanno, F. Marin, Y. Morel
667 from LEGOS. We particularly thank Tom Farrar (WHOI) and an anonymous reviewer for their
668 constructive comments, and J. Verron (IGE), C. Menesguen (LOPS), and X. Capet (LOCEAN) for their
669 time, and their fruitful comments. M. Tchilibou is funded by Université de Toulouse 3. L. Gourdeau,
670 G. Sérazin are funded by IRD; R. Morrow is funded by CNAP, and B. Djath was funded by CNES. This
671 work is a contribution to the joint CNES/NASA SWOT project “SWOT in the tropics” and is supported
672 by the French TOSCA programme.

673

674 **Annexe 1 Model configurations used in this study**

675 **- Global Model at 1/12°**

676 The model used is the ORCA12.L46-MAL95 configuration of the global 1/12° OGCM developed and
677 operated in the DRAKKAR consortium (www.ifremer.fr/lpo/drakkar) (Lecointre et al, 2011). The
678 numerical code is based on the oceanic component of the NEMO (Nucleus for European Modelling of
679 the Ocean) system (Madec, 2008). The model formulation is based on standard primitive equations.
680 The equations are discretized on the classical isotropic Arakawa C grid using a Mercator projection.
681 Geopotential vertical coordinates are used with 46 levels with a 6m resolution in the upper layers
682 and up to 250 m in the deepest regions (5750 m). The “partial step” approach is used (Adcroft et al.,
683 1997) to allow the bottom cells thickness to be modified to fit the local bathymetry. This approach
684 clearly improves the representation of topography effects (Barnier et al. 2006; Penduff et al. 2007).
685 The bathymetry was built from the GEBCO1 dataset
686 (http://www.gebco.net/data_and_products/gebco) for regions shallower than 200m and from

687 ETOPO2 (www.ngdc.noaa.gov/mgg/global/relief/ETOPO2) for regions deeper than 400m (with a
688 combination of both datasets in the 200m-400m depth range). Lateral boundary conditions for
689 coastal tangential velocity have a strong impact on the stability of boundary currents (Verron and
690 Blayo, 1996). Based on sensitivity experiments, a "partial-slip" condition is chosen, where the coastal
691 vorticity is not set to 0 ("free slip" condition), but is weaker than in the "no-slip" condition. The
692 atmospheric forcing (both mechanical and thermodynamical) is applied to the model using the CORE
693 bulk-formulae approach (Large and Yeager, 2004, 2009). The simulation started from rest in 1978
694 with initial conditions for temperature and salinity provided by the 1998 World Ocean Atlas (Levitus,
695 1998). It was spun up for 11 years using the CORE-II forcing dataset and then integrated from 1989 to
696 2007 using a 3-hourly ERA-interim forcing (Dee et al., 2011).

697 - Regional Model at 1/36° with and without tides

698 As part of the CLIVAR/SPICE program, regional simulations of the Solomon Sea in the South Western
699 tropical Pacific have been performed (Ganachaud et al., 2014). The numerical model of the Solomon
700 Sea used in this study has a 1/36° horizontal resolution, and 75 vertical levels. It is based on the same
701 oceanic component as the NEMO system presented above. This 1/36° resolution model is embedded
702 into the global 1/12° ocean model presented above and one-way controlled using an open boundary
703 strategy (Tréguier et al., 2001). Its horizontal domain is shown on Fig. 8. The bathymetry of the high-
704 resolution Solomon Sea model is based on the GEBCO08 dataset. Atmospheric boundary conditions,
705 consisting in surface fluxes of momentum, heat and freshwater, are diagnosed through classical bulk
706 formulas (Large and Yeager, 2009). Wind and atmospheric temperature and humidity are provided
707 from the 3-hourly ERA Interim reanalysis (Dee et al., 2011). A first version of the regional model with
708 45 vertical levels has been initialized with the climatological mass field of the World Ocean Atlas
709 (Levitus et al., 1998) and was integrated from 1989 to 2007. More technical details on this
710 configuration may be found in Djath et al. (2014). The new version used here is distinct from the
711 former version by the number of vertical levels (75 levels in the new version) but above all by its
712 ability to take account realistic tidal forcing (Tchilibou et al., 2018). The model is forced at the open
713 boundary by prescribing the first 9 main tidal harmonics (M2, S2, N2, K2, K1, O1, P1, Q1, M4) as
714 defined from the global tides atlas FES2014 (Lyard et al., 2018) through a forced gravity wave
715 radiation condition. The model is initialized by the outputs from the ORCA 1/12° version.

716 **Annexe 2 : Spectral sensitivity tests**

717 We tested the sensitivity of our G12d5 model's SSH wavenumber spectrum to different tapering
718 windows and the double periodic method, using different data length sizes, and in one or two
719 dimensions. The following steps were performed for these test spectra, evaluated within 10°S-
720 10°N/160°W-120°W: the model data are extracted meridionally and zonally in fixed segment lengths
721 of 5°, 10°, 20° and within a 20°X20° square box; the mean and linear trend (fitted plane for two-
722 dimensional case) were removed from each data segment or box; the filter window (Tk01, Tk05,
723 Hann) or Dbp are applied ; temporal and spatial (longitude, latitude) series spectra are calculated and
724 averaged in Fourier space. The results are shown in Fig. A1.

725 Tk01 meridional spectra in the tropics are the most perturbed by the short segment lengths (Fig.
726 A1a). In the 70-250 km range commonly used to define a global mesocale band (delimited by the
727 green vertical lines), the spectral slope flattens as the data segment length decreases. 5° segment
728 spectra with a Tk01 window have a $k^{-1.3}$ slope, which explains the very shallow slope in the tropics

729 observed by Dufau et al. 2016 who applied this short data segment size and a Tk01 window.
730 Meridional spectra differ primarily at larger scales from 100-500 km, when short segment lengths are
731 used (Fig. A1a). A comparison of the meridional spectrum using 20° segments and different windows
732 (Tk01, Tk05, Hann and Dbp) are shown in Figure A1b. Even with the 20° segments, Tk01 is distorted.
733 On the other hand, the Tk05, Hann and Dbp match well, with a near linear cascade of energy over
734 the 30-1000 km wavelength range, and are more adapted for the tropics since they capture the main
735 range of SSH mesoscale dynamics, particularly the spectral energy peaks around 1000 km
736 wavelength.

737 Similar calculations were performed for the zonal spectra (not shown) and confirm that the Tk01
738 method deforms the zonal spectra and flattens the spectral slope within the 70-250 km wavelength
739 band as the data segment size decreases. Tk05, Hann and Dbp 20° segment spectra match, although
740 the Dbp has more noise at small scale.

741 We also conducted a sensitivity test in the off-equatorial region (not shown): Flattening and
742 deformation of the spectrum by Tk01 persist, but the 10° segments or 10° square box are long
743 enough to capture the off-equatorial dynamics.

744 The particular sensitivity of spectra in the tropics to the choice of spectral segment length and
745 windowing is linked to energetic EKE and SSH signals extending out to longer wavelengths, and their
746 spectral leakage from low to high wavenumbers. Tk01 gives the worst performance in the tropics,
747 and the distortion of spectra is amplified for short data segments. Both the Tk05 and the Hann
748 windowing are a good compromise for preserving much of the original signal and reducing leakage,
749 but they need to be applied over larger segments.

964

965 Figure 1: a) Spatial distribution of altimetric alongtrack SSH wavenumber spectral slope calculated in
966 the fixed 70-250 km mesoscale range (from Xu and Fu, 2011; their Fig. 2). b) Latitudinal dependence
967 of the altimetric SSH alongtrack wavenumber spectra in the Atlantic Ocean (from Dufau et al., 2016;
968 their Fig. 3). The colors of the spectra refer to the geographical boxes where alongtrack data were
969 averaged on the right.

970 Figure 2: Snapshot of relative vorticity of the 1/12° G12d5 simulation. unit in $1.E5 s^{-1}$. The yellow lines
971 delineate the equatorial and off-equatorial regions. The dashed lines delineate square boxes for the
972 different regions to compute wavenumber spectra. The black arrows illustrate the main zonal
973 tropical currents (SEC: South Equatorial Current, SECC: South Equatorial CounterCurrent, NECC:
974 North Equatorial CounterCurrent, NEC: North Equatorial Current, STCC: SubTropical CounterCurrent,
975 HLCC: Hawaii Lee Counter Current).

976 Figure 3: a) latitudinal distribution of the EKE Frequency power spectra computed at each model grid
977 point of the G12d5 simulation, and averaged in longitude. The black line is the critical period from Lin
978 et al. (2008). b) longitudinal distribution of the EKE Frequency power spectra computed at each
979 model grid point of the G12d5 simulation, and averaged between 20°S-20°N. Units are in \log_{10} of
980 $cm^2/s^2/cpday$.

981 Figure 4: Zonal wavenumber-frequency EKE spectra averaged over a) 10°N-20°N region, b) 10°S-10°N
982 region, and c) 10°S-20°S region. d) Meridional wavenumber-frequency EKE spectra covering 20°S-
983 20°N averaged over the 120°W-150°W region. Superimposed on a) and c) are the theoretical
984 dispersion curves for the first mode baroclinic waves. Superimposed on b) are the theoretical
985 dispersion curves for the first 3 baroclinic wave modes, and the Kelvin wave mode. Units are in \log_{10}
986 of $cm^2/s^2/cpday/cpkm$.

987 Figure 5: Zonal wavenumber EKE spectra averaged over the equatorial (orange line), and off-
988 equatorial latitude bands (north: green; south: blue). Units are in $cm^2/s^2/cpkm$.

989 Figure 6: zonal (orange), meridional (green); and magnitude (blue) EKE wavenumber spectra
990 averaged over a) 10°N-20°N, b) 10°S-10°N, and c) 10°S-20°S regions. The magnitude geostrophic EKE
991 wavenumber spectra is also shown (EKEg, blue dash line). The vertical green dash lines delineate the
992 fixed 70-250 km mesoscale range. For reference, k^{-2} and k^{-3} curves are plotted (black lines). Units are
993 in $cm^2/s^2/cpkm$.

994 Figure 7: Meridional SSH wavenumber spectra averaged over the equatorial (orange), and off-
995 equatorial latitude bands (north: green, south:blue) for the G12d5 simulation (line). Topex-Poseidon
996 along track altimetric SSH wavenumber spectra are averaged over the same latitude bands (dash).
997 Units are in $cm^2/cpkm$.

998 Figure 8: SSH variability of the 1/36° regional model with explicit tides (R36Th) over the 3 month
999 simulation for a) the mesoscale signal, and b) the internal waves and internal tides defined by a 48 hr
1000 cutoff period. Units in cm^2 . The SARAL/AltiKA (black line) and Jason-2 (dash line) tracks used to
1001 compute the altimetric spectra in Fig. 10 are superimposed.

1002 Figure9: Meridional SSH wavenumber spectra averaged over 163°E-165°E for the hourly outputs of
1003 the 1/36° resolution regional model without tides (R36h, green), and 5 day averaged outputs (R36d5,
1004 orange). Meridional SSH spectra of the G12d5 simulation is in cyan. SSH meridional wavenumber
1005 spectra for the hourly outputs of the 1/36° regional model with explicit tides once the barotropic
1006 tides has been removed (R36Th-BT, in blue). The spectrum of the coherent baroclinic tides has been
1007 added to the spectrum of the model without tides (R36h+BC, purple), the contribution of the only
1008 M2 coherent baroclinic tide is in red (R36h+M2BC). The difference between the blue and purple
1009 curves corresponds with the incoherent internal tides. The corresponding along track SSH altimetric
1010 spectra for SARAL/AltiKa (line) and Jason-2 (dash) are in black. Units are in cm^2/cpkm .

1011
1012 Figure A1: Sensitivity experiments for different spectral processing techniques applied to meridional
1013 SSH wavenumber spectra representative of the equatorial region. a) SSH wavenumber spectra using
1014 a Tukey 0.1 window (blue) and a Tukey 0.5 window (red) depending on segment lengths: 5° (dots),
1015 10° (dash), 20° (line). b) SSH wavenumber spectra using different windowing over a 20° segment
1016 length: Tukey 0.1 window (Tk01, blue), Tukey 0.5 window (Tk05, red), Hanning window (Han, green).
1017 The double periodic method (Dbp, black) is also tested. For reference k^{-1} and k^{-5} curves are plotted.
