27 **Abstract**

28 The processes that contribute to the flat Sea Surface Height (SSH) wavenumber spectral slopes
29 observed in the tropics by satellite altimetry are examined in the tropical Pacific. The tropical
30 dynamics are first investigated with a $1/12^\circ$ global model. The equatorial region from $10^\circ\text{N} - 10^\circ\text{S}$ is
31 dominated by Tropical Instability Waves with a peak of energy at 1000 km wavelength, strong
32 anisotropy, and a cascade of energy from 600 km down to smaller scales. The off-equatorial regions
33 from $10\text{-}20^\circ$ latitude are characterized by a narrower mesoscale range, typical of mid latitudes. In the
34 tropics, the spectral taper window and segment lengths need to be adjusted to include these larger
35 energetic scales. The equatorial and off-equatorial regions of the $1/12^\circ$ model have surface kinetic
36 energy spectra consistent with quasi-geostrophic turbulence. The balanced component of the
37 dynamics slightly flatten the EKE spectra, but modeled SSH wavenumber spectra maintain a steep
38 slope that does not match the observed altimetric spectra. A second analysis is based on $1/36^\circ$ high-
39 frequency regional simulations in the western tropical Pacific, with and without explicit tides, where
40 we find a strong signature of internal waves and internal tides that act to increase the smaller-scale
41 SSH spectral energy power and flattening the SSH wavenumber spectra, in agreement with the
42 altimetric spectra. The coherent M2 baroclinic tide is the dominant signal at ~ 140 km wavelength. At
43 short scales, wavenumber SSH spectra are dominated by incoherent internal tides and internal waves
44 which extend up to 200 km in wavelength. These incoherent internal waves impact on space scales
45 observed by today's alongtrack altimetric SSH, and also on the future SWOT 2D swath observations,
46 raising the question of altimetric observability of the shorter mesoscale structures in the tropics.

47

48

49 1. Introduction

50 Recent analyses of global sea surface height (SSH) wavenumber spectra from alongtrack altimetric
51 data (Xu and Fu, 2011, 2012; Zhou et al., 2015) have found that while the mid-latitude regions have
52 spectral slopes consistent with quasi-geostrophic (QG) theory or surface quasi-geostrophic (SQG)
53 theory, the tropics were noted as regions with very flat spectral slopes (Fig. 1a). The objective of this
54 paper is to better understand the processes specific to the tropics that contribute to the SSH
55 wavenumber spectral slopes observed by satellite altimetry, particularly in the “mesoscale” range at
56 scales < 600 km, 90 days (Tulloch et al., 2009).

57
58 Only a few studies have addressed the tropical dynamics at spatial scales smaller than this 600 km
59 cutoff wavelength. The tropics are characterized by a large latitude-dependent Rossby deformation
60 radius (L_d) varying from 80 km at 15° to 250 km in the equatorial band and theoretically infinity at
61 the equator. Different studies have clearly distinguished the tropical regions dominated by linear
62 planetary waves from the mid-latitudes dominated by non-linear regimes (Fu, 2004; Theiss, 2004;
63 Chelton, 2007). Close to the equator, baroclinic instability is inhibited while barotropic instability
64 becomes more important (Qiu and Chen 2004), and mesoscale structures arise from the baroclinic
65 and barotropic instabilities associated with the vertical and horizontal shears of the upper circulation
66 (Ubelmann and Fu, 2011; Marchesiello et al., 2011). This distinct regime in the tropics raises many
67 questions on the representation of the meso/submesoscale tropical dynamics in the global analyses
68 of alongtrack altimetric wavenumber spectra. How are these complex, f -variable zonal currents
69 folded into alongtrack wavenumber spectra, calculated in $10 \times 10^\circ$ bins with a dominant meridional
70 sampling in the tropics? Also, the tropics are characterized by strong ageostrophic flow, and the
71 representativeness of SSH to infer the tropical dynamics needs to be checked.

72
73 Another dynamical contribution that could flatten the SSH wavenumber spectra in the tropics is
74 associated with high-frequency processes. In altimetric SSH data, the high-frequency barotropic tides
75 are corrected using global barotropic tidal models, and in the tropics away from coasts and islands,
76 these barotropic tide corrections are quite accurate (Stammer et al., 2014). Altimetric data are also
77 corrected for the large-scale rapid barotropic response to high-frequency atmospheric forcing (< 20
78 days), the so-called Dynamical Atmospheric Correction, using a 2D barotropic model forced by high-
79 frequency winds and atmospheric pressure (Carrere and Lyard, 2003). With only 10 to 35-day repeat
80 sampling, altimetry cannot track the evolution of these rapid barotropic processes, and a correction
81 is applied to prevent aliasing of their energy into lower frequencies. In addition to these large-scale
82 barotropic corrections which are removed from the altimetric data, there exist high-frequency SSH
83 signals from internal tides and internal waves that contribute energy at small scales < 300 km
84 wavelengths. Their impact on SSH wavenumber spectra has been predicted from model analyses in
85 different regions (Richman et al., 2012, Ray and Zaron, 2016), and show that they can dominate in
86 regions of low eddy energy. Dufau et al. (2016) demonstrated that unresolved internal tides can
87 introduce spectral peaks in the altimetric wavenumber spectra from 100-300 km wavelength, and
88 can exceed the level of the internal dynamics especially at low latitudes (Fig. 1b). Recent results from
89 a high-resolution $1/48^\circ$ model highlight that the tidal and supertidal signals in one region of the
90 equatorial Pacific greatly exceed the internal dynamics at scales less than 300 km wavelength (Savage
91 et al. 2017).

92 A more technical contribution that can impact on the lower spectral slopes in the tropics concerns

93 the altimetric data processing, the spectral calculation and spectral slope estimation. Much attention
94 has been devoted to the effects of altimetric noise (Xu and Fu, 2012; Zhou et al., 2015, Biri et al.,
95 2016) which can flatten the spectral slope calculation if the noise is not removed correctly. Different
96 studies also use different tapering windows to reduce leakage of non-periodic signals in limited-
97 length data series, which can also modify the spectral slope. In global studies, a fixed wavelength
98 band from 70-250 km is often used for the spectral slope calculation (Xu and Fu, 2012; Dufau et al.,
99 2016), which is appropriate for estimating the spectral slope of the energy cascade at mid-latitudes,
100 but may not be well-adapted for the tropics where the maximum spectral slope extends at longer
101 wavelengths, due to the larger Rossby radius there (Fig. 1b).

102

103 Thus, the interpretation of altimetric tropical SSH spectra, at spatial scales smaller than 600 km,
104 remains a matter of debate in terms of ocean dynamics. This paper aims at filling this gap by studying
105 the dynamical processes contributing to the small-scale SSH spectra in the tropical Pacific using
106 modeling and observational data. Two different approaches are proposed to better understand the
107 contributions to the observed altimetric flatter spectral slopes. Firstly, we wish to explore the
108 spectral signatures in SSH and EKE of the tropical Pacific mesoscale dynamics (with periods greater
109 than 10 days and wavelengths down to 25 km) and we will concentrate particularly on the tropical
110 “mesoscale” band that varies with latitude. For this, we analyse the global $1/12^\circ$ DRAKKAR model in
111 the tropical Pacific from 20°S to 20°N , using 5 day outputs covering the period 1987-2001. In
112 comparison to the altimetric analyses of Xu and Fu (2012) or Dufau et al. (2016), this model was
113 specifically chosen to have no high-frequency response to tides, internal waves or rapid tropical
114 waves, and is not limited at low wavelengths by the altimetric instrument noise, but rather by the
115 horizontal grid resolution. We will also use this model to explore the effects of using limited segment
116 lengths or specific windowing when calculating our wavenumber spectra.

117 In the second part of this paper, we will address the impact on SSH and EKE of the high-frequency
118 components using a unique modelling experiment: we will analyze a higher resolution and high-
119 frequency version of the model: a $1/36^\circ$ regional model of the south west Pacific (Djath et al., 2014)
120 with and without tides. These two regional model runs have exactly the same configuration and high-
121 frequency atmospheric forcing, both versions include the atmospherically forced internal gravity
122 waves in the tropics. Careful filtering of the barotropic and coherent internal tides from the model
123 with tides also allows us to explore the relative impact of the incoherent tide-ocean circulation
124 interactions, and their signature on the alongtrack wavenumber spectra. This two-model
125 configuration allows us to make a brief investigation of the effects of high-frequency dynamics on the
126 wavenumber spectra, and to discuss the modeled spectra in comparison with altimetric wavenumber
127 spectra based on Topex/Poseidon, Jason and Saral/AltiKa altimeter data. These results will help to
128 better understand the physical content of altimetric observation today, as well as to explore the finer
129 scales that would be captured using future measurements of the SWOT satellite (Fu and Ubelmann,
130 2014).

131 In section 2, the different models and data used are presented. In section 3, we discuss processing
132 issues for the spectral calculation, particularly to reduce leakage effects in short tropical segments. In
133 section 4, we discuss the EKE spectral signature of the dynamics over the tropical Pacific as simulated
134 by the $1/12^\circ$ resolution model. In section 5, results are discussed in term of balanced dynamics and
135 the $1/12^\circ$ model’s SSH spectra are compared to Jason and Saral AltiKa wavenumber spectra. Finally,
136 the contribution of the high-frequency motions to the SSH spectral signature are investigated using

137 the $1/36^\circ$ regional resolution model with and without tides, to illustrate its close match with
138 altimetric data. Section 6 presents the conclusions of our study.

139

140 **2 Models, and altimetric data**

141 **2.1 Models**

142 To study mesoscale and submesoscales activity from an OGCM, the model has to properly resolve the
143 corresponding dynamical scales (i.e., be eddy-resolving). The effective resolution for numerical
144 models is that 6-8 grid points are needed to properly resolve dynamical features (Soufflet et al.,
145 2016). In mid latitudes numerical convergence requires \sim km horizontal resolution, however in the
146 tropics, because of the larger L_d due the weaker Coriolis force, numerical convergence is obtained
147 from $1/12^\circ$ horizontal resolution, and the increase of resolution to $1/36^\circ$ only seems to displace the
148 dissipative range of the model toward smaller scale (Marchesiello et al., 2011). In this paper, we first
149 use a global model at $1/12^\circ$ resolution, and in a second part we use a regional $1/36^\circ$ model resolution
150 to investigate the impact of high frequency ageostrophic motions such as baroclinic tides and
151 internal waves.

152 **- Global Model at $1/12^\circ$**

153 The model used is the ORCA12.L46-MAL95 configuration of the global $1/12^\circ$ OGCM developed and
154 operated in the DRAKKAR consortium (www.ifremer.fr/lpo/drakkar) (Lecointre et al, 2011). The
155 numerical code is based on the oceanic component of the NEMO (Nucleus for European Modelling of
156 the Ocean) system (Madec, 2008). The model formulation is based on standard primitive equations.
157 The equations are discretized on the classical isotropic Arakawa C grid using a Mercator projection.
158 Geopotential vertical coordinates are used with 46 levels with a 6m resolution in the upper layers
159 and up to 250 m in the deepest regions (5750 m). The "partial step" approach is used (Adcroft et al.,
160 1997) to allow the bottom cells thickness to be modified to fit the local bathymetry. This approach
161 clearly improves the representation of topography effects (Barnier et al. 2006; Penduff et al. 2007).
162 The bathymetry was built from the GEBCO1 dataset
163 (http://www.gebco.net/data_and_products/gebco) for regions shallower than 200m and from
164 ETOPO2 (www.ngdc.noaa.gov/mgg/global/relief/ETOPO2) for regions deeper than 400m (with a
165 combination of both datasets in the 200m-400m depth range). Lateral boundary conditions for
166 coastal tangential velocity have a strong impact on the stability of boundary currents (Verron and
167 Blayo, 1996). Based on sensitivity experiments, a "partial-slip" condition is chosen, where the coastal
168 vorticity is not set to 0 ("free slip" condition), but is weaker than in the "no-slip" condition. The
169 atmospheric forcing (both mechanical and thermodynamical) is applied to the model using the CORE
170 bulk-formulae approach (Large and Yeager, 2004, 2009).

171 The simulation started from rest in 1978 with initial conditions for temperature and salinity provided
172 by the 1998 World Ocean Atlas (Levitus, 1998). It was spun up for 11 years using the CORE-II forcing
173 dataset and then integrated from 1989 to 2007 using a 3-hourly ERA-interim forcing (Dee et al.,
174 2011). The 3D velocities, and the 2D Sea Surface Height (SSH) are saved as 5-day means during the
175 period of integration. In the following, it is referenced as G12d5. The domain considered in this study
176 covers the tropical Pacific between 20°N - 20°S . This simulation has been used to document

177 mesoscale variability in the South West Pacific Solomon Sea (Gourdeau et al., 2014; Gourdeau et al.,
178 2017). The present study will analyse this simulation over the tropical Pacific.

179 - Regional Model at 1/36° with and without tides

180 As part of the CLIVAR/SPICE program, regional simulations of the Solomon Sea in the South Western
181 tropical Pacific have been performed (Ganachaud et al., 2014). The numerical model of the Solomon
182 Sea used in this study has a 1/36° horizontal resolution, and 75 vertical levels. It is based on the same
183 oceanic component as the NEMO system presented above. This 1/36° resolution model is embedded
184 into the global 1/12° ocean model presented above and one-way controlled using an open boundary
185 strategy (Tréguier et al., 2001). Its horizontal domain is shown on Fig. 3b. The bathymetry of the high-
186 resolution Solomon Sea model is based on the GEBCO08 dataset. Atmospheric boundary conditions,
187 consisting in surface fluxes of momentum, heat and freshwater, are diagnosed through classical bulk
188 formulas (Large and Yeager, 2009). Wind and atmospheric temperature and humidity are provided
189 from the 3-hourly ERA Interim reanalysis (Dee et al., 2011). A first version of the regional model with
190 45 vertical levels has been initialized with the climatological mass field of the World Ocean Atlas
191 (Levitus et al., 1998) and was integrated from 1989 to 2007. More technical details on this
192 configuration may be found in Djath et al. (2014). The new version used here is distinct from the
193 former version by the number of vertical levels (75 levels in the new version) but above all by its
194 ability to take account realistic tidal forcing (Tchilibou et al., 2018). It is of particular importance in
195 this area where internal tides are particularly active (Niwa and Hibiwa, 2011; Gourdeau, 1998), and
196 could modify accordingly the energy flux for the meso and submesoscale bands (Richman et al.,
197 2012). The model is forced at the open boundary by prescribing the first 9 main tidal harmonics (M2,
198 S2, N2, K2, K1, O1, P1, Q1, M4) as defined from the global tides atlas FES2014 (Lyard et al., 2018)
199 through a forced gravity wave radiation condition. The model is initialized by the outputs from the
200 ORCA 1/12° version. Two simulations are performed: one without the tidal forcing (R36) over the
201 1992-2012 period, and one with the tidal forcing (R36T) over the 1992-2009 period. Model outputs
202 are saved as daily mean (R36(T)d), and instantaneous fields are saved hourly (R36(T)h) during a 3
203 month period from January-March 1998.

204 2.2 Altimetric data

205 Along-track SSH observations from TOPEX/Poseidon covering a period (January 1993 to December
206 2001) in common with the G12d5 simulations are analyzed over the tropical Pacific domain. The
207 most recent altimetric missions (Jason-2 and SARAL/Altika) are also analyzed over the January-2013
208 to December-2014 period to compare with the signature of the high frequency modelled SSH in
209 R36Th. These data are made available from the Copernicus Marine and Environment Monitoring
210 Service (CMEMS, <http://marine.copernicus.eu>). TOPEX/Poseidon and Jason-2 are conventional pulse-
211 width limited altimeters operating in the Ku-band (Lambin et al., 2010). SARAL/Altika with its 40 Hz
212 Ka-band emitting frequency, its wider bandwidth, lower orbit, increased Pulse Repetitivity Frequency
213 and reduced antenna beamwidth, provides a smaller footprint and lower noise than the Ku-band
214 altimeters (Verron et al., 2015). For the different missions we will analyze the 1 Hz data, extracted
215 over the same region as our model analysis.

216

217 3 Spectral methods

218 In the following sections we present spectral analyses of the modelled SSH or EKE fields, or the
219 altimetric SSH. The spectral analysis we use is based on Fast Fourier Transforms (FFT) of our signal,
220 which allows us to work with a limited sampled signal. Longer data records enable a better
221 decomposition of the variability at each frequency (wavenumber) and thus a better separation of
222 neighboring frequencies in the spectrum. However, for wavenumber spectra, long spatial data
223 records can mix information from different geographical regimes, especially in the tropics where
224 meridional sections cross the strong zonal currents, making their dynamical interpretation difficult.

225

226 Different studies performing spectral analysis of altimetric data or models over the global ocean use
227 very different data length segments to calculate the spectrum. Some altimetric studies use data
228 segment lengths of around 500 km (e.g. Dufau et al., 2016), or 1000 km length tracks averaged in 10°
229 or 20° square box, with or without overlapping (Xu and Fu, 2012). Model spectra (isotropic) are
230 mostly calculated in 10° or 20° square boxes (e.g., Sasaki and Klein, 2012; Biri et al., 2016; Chassignet
231 and Xu, 2017). These data segment lengths may be adequate for the mid-latitudes but are not
232 appropriate for the tropics, when the maximum energy can occur at 600-1000 km wavelengths.
233 Using shorter segments than this reduces the maximum energy and thus the spectral slope. A wide
234 variety of filter windows are applied in the different studies before calculating frequency
235 (wavenumber) spectra to reduce the leakage effect. These include the 10 % cosine taper window or
236 Tukey 0.1 window, referred hereafter as Tk01 (LeTraon et al., 2008; Richman et al., 2012; Dufau et
237 al., 2016); the Hanning window, referred as Han (Capet et al., 2008; Rocha et al., 2016); or making
238 the signal double periodic instead of the tapering, referred as Dbp (Marchesiello et al. 2011; Sasaki
239 and Klein, 2012; Chassignet and Xu, 2017). In the following, we will also consider the Tukey 0.5
240 window (Tk05).

241

242 We tested the sensitivity of our G12d5 model's SSH wavenumber spectrum to the different tapering
243 windows and the double periodic method, using different data length sizes, and in one or two
244 dimensions. The following steps were performed for these test spectra, evaluated within 10°S-
245 10°N/160°W-120°W: the model data are extracted meridionally and zonally in fixed segment lengths
246 of 5°, 10°, 20° and within a 20°X20° square box; the mean and linear trend (fitted plane for two-
247 dimensional case) were removed from each data segment or box; the filter window (Tk01, Tk05, Han)
248 or Dbp are applied ; temporal and spatial (longitude, latitude) series spectra are calculated and
249 averaged in Fourier space. The results are shown in Fig. 2.

250 Tk01 meridional spectra in the tropics are the most perturbed by the short segment lengths (Fig. 2a).
251 In the 70-250 km range commonly used to define a global mesoscale band (delimited by the green
252 vertical lines), the spectral slope flattens as the data segment length decreases. 5° segment spectra
253 with a Tk01 window have a $k^{-1.3}$ slope, which explains the very shallow slope in the tropics observed
254 by Dufau et al. 2016 who applied this short data segment size and a Tk01 window. Meridional
255 spectra differ primarily at larger scales from 100-500 km, when short segment lengths are used (Fig.
256 2a). A comparison of the meridional spectrum using 20° segments and different windows (Tk01,
257 Tk05, Han and Dbp) are shown in Figure 2b. Even with the 20° segments, Tk01 is distorted. On the
258 other hand, the Tk05, Han and Dbp match well, with a near linear cascade of energy over the 30-
259 1000 km wavelength range, and are more adapted for the tropics since they capture the main range
260 of SSH mesoscale dynamics, particularly the spectral energy peaks around 1000 km wavelength.

261 Similar calculations were performed for the zonal spectra (not shown) and confirm that the Tk01
262 method deforms the zonal spectra and flattens the spectral slope within the 70-250 km wavelength
263 band as the data segment size decreases. Tk05, Han and Dbp 20° segment spectra match, although
264 the Dbp has more noise at small scale.

265 We also conducted a sensitivity test in the off-equatorial region (not shown): Flattening and
266 deformation of the spectrum by Tk01 persist, but the 10° segments or 10° square box are long
267 enough to capture the off-equatorial dynamics.

268 The particular sensitivity in the tropics to the spectral segment length and windowing is linked to
269 energetic EKE and SSH signals extending out to longer wavelengths. The discrepancies between the
270 different window filters used result from the way they modify the original data. Tk01 preserves more
271 of the long wavelength signal in the original data. However it creates unrealistic variability at shorter
272 wavelengths because of its abrupt transition to zero at the edge of segments. This effect is amplified
273 for short data segments, resulting in more important variability at small scale (for wavelengths near
274 10 % of the data size). Thus there is more spurious energy near 55 km wavelength for the Tk01 with 5
275 degree (550 km) segments, near 110 km for the 10° segments, and near 220 km for the 20° segments
276 (Fig. 2a). The Tk01 abrupt transition to zero combines with the low wavenumber leakage and distorts
277 the spectra. There is a minor difference between Tk05 and Han, depending on data variability. The
278 advantage of Tk05 is in retrieving the large-scale peaks which are smoothed with the Hanning filter
279 window. Tk05 is a good compromise for preserving much of the original signal and reducing leakage,
280 but needs to be applied over larger segments. The Dbp technique compares well to Tk05 and Han for
281 one-dimensional spectra. The only problem with this method is the difference at the large-scale and
282 unfiltered spectral fluctuations at small scale.

283 We conclude that the Tk05 or Hanning filters give similar results in the equatorial band, with a
284 minimum of 15° to 20° needed in segment lengths. We do not advise to use the tk01 filter window,
285 and we choose to use the Tukey 0.5 filter in the paper. In the off-equator region, 10° data segments
286 or 10°X10° boxes are sufficient.
287

288 **4 Spectral representation of the tropical dynamics**

289 In this section we analyze the spectral signatures of the tropical dynamics by first considering the
290 surface velocity fields of the G12d5 simulation over the open Pacific Ocean. Modeling studies mainly
291 analyze velocity or EKE fields, and we start our spectral analysis by checking that the model
292 represents well the main dynamical processes in the tropics. Surface velocity fields were averaged
293 over the first 40 m depth and include geostrophic and ageostrophic components. The model resolves
294 a domain of variability with periods greater than 10 days, and wavelengths exceeding 25 km, but
295 model dissipation may be active up to 70 km wavelength. Note that the resonant response to the
296 wind forcing through the 3-5 day period, large-scale equatorially trapped inertia-gravity waves, are
297 not represented in G12d5 because of the 5-day averaged model outputs.

298 The Tropical Pacific is characterized by a series of strong alternate zonal currents and a large range of
299 ocean variability, in response to the atmospheric forcing and to the intrinsic instability of the current
300 system. The main zonal currents spanning the tropical Pacific are shown in Fig. 3: North of 10°N is the
301 westward North Equatorial Current (NEC) and at its northern edge are the eastward SubTropical

302 CounterCurrent (STCC) and the Hawaiian Lee CounterCurrent (HLCC) (Kobashi and Kawamura, 2002;
303 Sasaki and Nonaka, 2006); between 3°-8°N is the eastward North Equatorial CounterCurrent (NECC);
304 South of 3°N, the westward South Equatorial Current (SEC) straddling the equator is divided in two
305 branches by the eastward Equatorial UnderCurrent (EUC) that reaches the surface to the east. The
306 eastward South Equatorial Counter Current (SECC) in the south western Pacific is between 6°-11°S.
307 Instabilities of these zonal currents result in meso and submesoscale activity illustrated by a snapshot
308 of vorticity (Fig. 3) that illustrates the description of vortices in Ubelmann and Fu (2011). It is
309 characterized by structures with a large range of scale and strong anisotropy in the equatorial band.
310 The largest structures (~500 km) correspond to the nonlinear Tropical Instability Vortices (TIVs), also
311 associated with the Tropical Instability Waves (TIWs), and occur north of the equator (Kennan and
312 Flament, 2000; Lyman et al., 2007). The off-equatorial regions (10-20° latitude) are characterized by
313 smaller-scale turbulent structures in Fig. 3.

314 In order to investigate how these well-known tropical dynamics project into frequency or
315 wavenumber spectra, we will analyze separately the equatorial band (10S-10°N) and the off-
316 equatorial band (10°N-20°N and 10°S-20°S) defined by the different boxes in Fig. 3. In the following,
317 the model's representation of the following diagnostics will be discussed together for the each zonal
318 band : the EKE frequency spectra as a function of latitude and longitude (Fig. 4), the zonal EKE
319 wavenumber-frequency (k - ω) spectra and meridional EKE wavenumber-frequency (l - ω) spectra (Fig.
320 5), and the 1D (zonal/meridional) EKE wavenumber spectra (Fig. 6).

321

322 4.1 Equatorial region

323 The temporal variability of the tropical EKE signal is shown by EKE frequency spectra as a function of
324 latitude and longitude in Fig. 4. In the equatorial band, most of the energy is concentrated within 5°
325 of the equator (Fig. 4a). The highest EKE occurs in this band at annual to interannual scales, but there
326 is still significant energy over all frequencies greater than the 10-days resolved by this model. EKE
327 spectra averaged in latitude over 20°N-20°S are highly influenced by the energetic equatorial
328 dynamics (Fig. 4b). This band includes the equatorial wave guide where waves tend to propagate
329 zonally and are organized into a set of discrete meridional modes (Farrar, 2008). Since zonal
330 wavenumber-frequency spectra are averaged from a number of latitudes within the equatorial band,
331 contributions from the different modes may be seen at once (Fig. 5b). The eastward phase speed
332 (positive wavenumber), due to fast moving Kelvin waves at the equator is visible even if the strong
333 westward propagation (negative wavenumber) just off the equator overpowers the eastward
334 propagation on the equator in the averaged spectrum. We have superimposed on the zonal
335 wavenumber-frequency spectrum the theoretical dispersion curves of the first baroclinic-Rossby
336 waves in a resting ocean. Values of wavenumber and frequency for which the EKE power spectrum is
337 significantly above the background follow relatively well the variance-weighted mean location of
338 dispersion curves for long equatorial waves. Meridional wavenumber-frequency (l - ω) EKE spectra
339 were computed over the 20°N to 20°S section, in different longitude bands spanning the Pacific
340 Ocean. Fig.5d shows an example for the particularly energetic 120°W-150°W band. Other longitude
341 bands across the Pacific show similar spectral energy patterns, but with lower energy levels. Figures
342 5b,d illustrate the strong anisotropy between the zonal (k , ω) and meridional (l , ω) spectra. The
343 meridional structure of the dominant zonal equatorial waves is well known, with meridional
344 amplitude decaying away from the equator over +/-5° or 550 km. This contributes in the meridional-

345 frequency EKE spectrum to the fairly constant decrease in spectral energy from long wavelengths
346 down to 100-250 km wavelength, in both north and south directions (Fig.5d).

347

348 The ridge of westward variance (Fig. 5b) is nearly vertical, with variance mainly restricted to large
349 wavelengths but also extending to high frequencies in relation with TIW activity. In accordance with
350 observations (Willet, 2006), the modeled TIWs are defined by periods and zonal wavelengths in the
351 range of 15-40 days and 800-2000 km, respectively, and have a meridional propagation with
352 northward and southward motion roughly balanced (Fig. 5d). The 33-day TIW variability is triggered
353 by baroclinic instability of the SEC-NECC system, located between 3°N-5°N and 160°W-120°W (Fig.
354 4a,b). They have an asymmetric structure across the equator with larger energy north of the equator
355 than south of it in accordance with the analysis of TOPEX/Poseidon sea level data by Farrar (2008).
356 The 20-25 days variability, associated with another type of TIW triggers by barotropic instability of
357 the EUC-SEC system (Masina et al., 1999), is centered at the equator, east of 140°W (Fig. 4a,b).
358 Centered at the equator, from the background there is a 60-80 days variability extending from 150°E
359 to 130°W (Fig. 4a,b) associated with intraseasonal Kelvin waves (Cravatte et al., 2003; Kessler et al.,
360 1995) as confirmed by eastward variance and energy centered at $l=0$ in the zonal and meridional-
361 frequency spectra, respectively (Fig. 5b,d).

362

363 The model represents these tropical signals well, and for wavelengths larger than 600 km the
364 equatorial waves are the dominant signal (Tulloch et al., 2009). For wavelengths smaller than 600
365 km, the variance no longer follows the Rossby wave dispersion curves, and exhibits a red noise
366 character in wavelength, and a nearly white noise in frequency. These rapid motions with 250-600
367 km wavelengths occur in response to wind forcing, wave interactions or current instability. The
368 corresponding zonal EKE wavenumber spectrum (Fig. 6) has a steep slope that continues rising to
369 long wavelengths with a k^3 relation reaching a peak at 1000 km, reflecting the zonal scales of the
370 TIWs, before flattening to a k^{-1} power law at larger scale. Below 70 km, EKE spectra drastically
371 steepen as an effect of model dissipation.

372 4.2 Off equatorial regions

373 Poleward of 10° the equatorial trapped waves become insignificant, and most of the energy is
374 concentrated at periods greater than 60 days (Fig. 4a). This corresponds with results by Fu (2004)
375 showing a decreasing frequency range with latitude, where the maximum frequency at each latitude
376 corresponds to the critical frequency of the first-mode baroclinic waves that varies from 60 days at
377 10°S to 110 days at 20°S (Lin et al., 2008). The zonal wavenumber-frequency spectrum strongly
378 differs from those in the equatorial belt (Fig. 5a,c), and is closer to the mid latitude spectra (Wunsch,
379 2010; Wakata, 2007; Fu, 2004) with smaller energy in the south tropics than in the north as also
380 reported by Fu (2004). The theoretical dispersion curves for mid latitude first baroclinic Rossby waves
381 are shown for the case of meridional wavenumbers corresponding to infinite wavelengths. At low
382 wavenumbers (i.e., long wavelengths > 600 km) the motions follow the baroclinic dispersion curves.

383 Although linear Rossby wave theory provides a first - order description of the EKE spectra, in both
384 hemispheres energy extends to higher frequencies (Fig. 4a), and as the wavenumber and frequency
385 increases, significant deviations from the baroclinic dispersion curves occur (Fig. 5a,c). Barotropic and
386 baroclinic instabilities, and nonlinear processes might generate energy at periods down to 20-30
387 days, prohibited by the linear dispersion relation (Hughes and Williams, 2010). Much of the energy

388 lies approximately along a straight line called the ‘non dispersive line’ in wavenumber–frequency
389 space as it implies non-dispersive motions. The wavenumber dependencies along the ‘non dispersive
390 line’ could be the signature of non-linear eddies. In fact, for eddies that retain their shapes as they
391 propagate, the energy at every wavenumber must propagate non-dispersively (Rhines, 1975). The
392 westward propagation speed is estimated at ≈ 10 cm/s, close to the eddy propagation speed found in
393 this latitudinal range by Fu (2009) and Chelton et al. (2007). But these regions are defined as a weakly
394 nonlinear regime (Klocker and Abernathy, 2014), and the non-dispersive line may account both for
395 coherent vortices and jet meanders propagating westward at an approximately uniform speed
396 (Morten et al., 2017). So our frequency-wavenumber spectra are consistent both with linear
397 dynamics at low wavenumbers but also with westward-propagating eddy-like coherent vortex
398 structures or jet meanders at higher wavenumbers.

399 The zonal EKE wavenumber spectra (Fig. 6) in the off equatorial regions exhibit a standard shape with
400 a long-wavelength plateau and a spectral break at about 300-400 km, following by a drop in energy
401 close to a k^2/k^3 relation (Stammer, 1997). These steep spectral slopes correspond with an inertial
402 range characteristic of mesoscale turbulence (Xu and Fu, 2011). These different spectra confirm that
403 the northern tropics are more energetic than the southern part with a mesoscale range extending to
404 larger scale. It quantifies the more active turbulence in the northern hemisphere, as illustrated in
405 Fig.3b.

406 **4.3 Anisotropic EKE spectra**

407

408 Classically, wavenumber spectra are investigated throughout an oceanic basin by dividing the basin
409 in square boxes where spectra are calculated to take account of the regional diversity of QG
410 turbulence properties (Xu and Fu, 2011; Sasaki and Klein, 2012; Biri et al., 2016; Dufau et al., 2016).
411 Here, the spectra analysis of the equatorial and off-equatorial bands described above is revisited in
412 $10^\circ \times 10^\circ$ boxes for the off-equatorial region, and in $20^\circ \times 20^\circ$ boxes for the equatorial region that are
413 suited to recover the shape of the mesoscale range in the tropics (e.g. section 3). Within each
414 equatorial or off equatorial latitude band, spectra in the different boxes are similar (not shown).
415 Therefore spectra are averaged over all the boxes and we present one mean spectrum
416 representative of the square boxes for each equatorial, and off equatorial bands. In geostrophic
417 turbulence, which is nondivergent to leading-order, isotropy implies that 1D (zonal/meridional) and
418 2D isotropic wavenumber spectra are identical and follow the same power law. In the tropics there is
419 a stronger anisotropic component of the dynamics, which will be explored in Fig.7.

420

421 When we concentrate on the $20^\circ \times 20^\circ$ equatorial box, we are limited to scales smaller than 2000 km,
422 and here the meridional EKE spectrum has a higher level of energy than the zonal one (Fig. 7b). It
423 reveals the energetic meridional perturbations due to instabilities of the larger-scale zonal currents.
424 The isotropic EKE spectrum is mostly representative of the meridional one. Note that since
425 alongtrack altimetry is mainly orientated in the meridional direction in the tropics, altimetric SSH
426 measurements are particularly well suited to account for the dominant meridional variability, within
427 the limit of the geostrophic hypothesis. Despite the anisotropy at every scale, the different EKE
428 spectral components have a similar shape, with a continuous k^{-3} slope between 100 and 600 km
429 wavelength. The peak of the EKE spectra corresponds to a wavelength of 1000 km. These modeling
430 results compare relatively well with the analysis of the submesoscale dynamics associated with the
431 TIWs by Marchesiello et al. (2011). They observe a peak of energy around 1000 km corresponding to

432 the TIW wavelength, and a linearly decay of the spectrum with a slope shallower than -3. It is
433 doubtful to define an inertial band in the equatorial region, but we can say that at wavelengths from
434 100-600 km, the EKE spectral slope of k^{-3} is consistent with a QG cascade of turbulence.

435

436 In the $10^\circ \times 10^\circ$ off-equatorial boxes, the energy at long wavelengths is greatly reduced compared to
437 the equatorial band. Yet the zonal, meridional and isotropic EKE spectra are similar for wavelengths
438 up to 250 km (Fig. 7a,c). Their slopes are steeper than k^{-2} at scales smaller than 250 km. So, poleward
439 of 10° the hypothesis of isotropy seems to be relevant for scales up to 250 km even if the flow is
440 supposed to be weakly nonlinear (Klocker and Abernathey, 2014). The peak of the EKE spectra
441 corresponds to a wavelength of 300 km. The EKE slope over the redefined mesoscale range from 100
442 to 250 km is between -2 and -3 which lies between the prediction of SQG and QG turbulence.

443

444 Our modeled zonal frequency-wavenumber spectra differ strongly across the equatorial and off
445 equatorial regions, but show a good representation of the tropical wave and TIW/TIV dynamics. The
446 slope of the ridge of westward variance in the zonal k - ω spectrum in Fig. 5 increases towards the
447 equator. As the slope becomes steeper, more power is concentrated at lower wavenumbers. The
448 change in slope of the ridge itself is related to the change in deformation radius and wave
449 propagation speed (Wortham and Wunsch, 2014). The equatorial region differs from the off
450 equatorial regions in having strong anisotropy with mainly zonally oriented structures (Fig. 7), higher
451 energy at long wavelength due to the strong activity of long equatorial waves, and an overlap
452 between geostrophic turbulence and Rossby wave time scales that produces long waves and slows
453 down the energy cascade to eddies with scales consistent in the tropics with a generalized Rhines
454 scale (L_r) (Theiss, 2004, Tulloch et al., 2009; Klocker et al., 2016; Eden, 2007).

455 Although geostrophy is not valid at the equator, it is valid poleward from 2° latitude, and since our
456 equatorial wavenumber spectral calculations are averaged or span over 20° in latitude, they include a
457 strong geostrophic component. Even so, the validity of geostrophic turbulence theory is questionable
458 in the equatorial band. Rather, our modeled spectral analysis shows the contrasts between the
459 equatorial and off-equatorial regions for the wavenumber range where a steep slope is observed. In
460 the weakly nonlinear regime of the off-equatorial regions, we find spectral slopes of k^{-2} / k^{-3} over a
461 short 100-250 km wavenumber range. The highly anisotropic, ageostrophic equatorial dynamics are
462 characterized by a peak of energy at 1000 km due to TIWs, and a large “mesoscale” range over 100-
463 600 km wavelength with a k^{-3} spectral slope.

464

465 **5 Modeled and altimetric SSH wavenumber spectra**

466 **5.1 Contribution from low-frequency dynamics**

467 Altimetric SSH only provides access to the balanced, geostrophic component of the surface flow (in
468 addition to signals from the high-frequency internal waves and tides, not included in the G12d5
469 version of the model used here). Since the tropical regions have a strong ageostrophic component of
470 the flow, we consider how the wavenumber spectra of geostrophic currents (EKEg) differ from that
471 of the total currents analyzed in section 4. Close to the equator, as f approaches zero, the
472 geostrophic current component can still be calculated using the beta approximation, following Picaut
473 et al. (1989). Fig.7 shows the difference between the wavenumber spectra calculated from the total

474 EKE averaged over the upper 40 m, and from the geostrophic component of EKE estimated at the
475 surface.

476 In the equatorial band at scales from 300 to 1000 km, the ageostrophic EKE is more energetic, with a
477 stronger contribution to the total EKE than the geostrophic component (Fig. 7b). In the off-equatorial
478 bands (Fig 7a,c), the geostrophic and total EKE spectra are similar at larger wavelengths. However, in
479 all regions, the total EKE is weaker than the geostrophic EKE at scales from 250 km down to the 20
480 km resolved by the model. Klein et al. (2008) also noted stronger geostrophic EKE at small
481 wavelengths (and weaker spectral slopes) compared to upper ocean EKE spectra in mid latitude
482 regions which had QG slope characteristics. In terms of spectral slope in the equatorial region, using
483 the geostrophic EKE rather than the total EKE tends to flatten the spectra in the 600-110 km
484 mesoscale range, and changes the spectral slope from k^{-3} to k^{-2} . In the off-equatorial regions, the
485 geostrophic EKE has a slightly flatter spectral slope between -2 and -3 in the 100-250 km band.

486

487 Since the altimetric groundtracks have a more meridional orientation in the tropics, the altimetric
488 SSH spectra should be like the model's meridional SSH spectra that are shown on Figure 8. SSH
489 meridional wavenumber spectra (Fig. 8) confirm that in the off-equatorial regions, the northern zone
490 has higher spectral power over all wavelengths, as expected from the EKEg spectra. Within the
491 wavelength band from 100 to 250 km both off-equatorial regions have SSH spectral slopes between
492 k^{-4} to k^{-5} (equivalent to k^{-2} - k^{-3} in EKE) similar to QG dynamics. The modelled SSH spectra show a
493 similar anisotropy in the equatorial zone as the EKE spectra, with a more energetic meridional SSH
494 spectrum than the zonal spectrum (not shown). Due to the strong ageostrophic component in the
495 equatorial region, SSH spectra exhibit lower spectral power than in the off-equatorial region. From
496 100 to 600 km, the SSH spectral slopes in the equatorial region are close to k^{-4} , consistent with the k^{-2}
497 spectral slopes in EKEg. The fixed wavelength band used by previous studies [70-250 km] can be
498 compared to this longer wavelength band. Using the fixed wavelength band leads to a slight
499 reduction in the low-frequency SSH spectral slope estimate, but without a drastic modification. These
500 results indicate that if the internal balanced dynamics of our $1/12^\circ$ model were the main contribution
501 to the altimetric SSH, then we would expect a k^{-4} (sQG) slope in the equatorial band, and closer to k^{-5}
502 (QG) in the off-equatorial band.

503 Fig. 8 also shows the alongtrack Topex/Poseidon SSH spectra over the same region and period as the
504 G12d5 simulation. The altimetric data are selected with the same segment lengths, and with the
505 same pre-processing and spectral filtering as in the model. In the equatorial and off-equatorial zones,
506 the altimetric SSH wavenumber spectra clearly exhibit the weaker k^{-2}/k^{-1} spectral slopes in the 70-250
507 km mesoscale range as described in previous studies (Xu and Fu, 2011,2012; Zhou et al., 2015). At
508 scales larger than our spectral slope range (600 km in the equatorial region, 200 km in the off-
509 equatorial zones), the model-altimeter spectra have similar shapes although the altimeter data has
510 higher spectral power. Potentially, the high-frequency < 10d rapid equatorial waves with longer
511 wavelengths are not included in the model, and may contribute to these differences. The spectral
512 peaks in the altimetric data at 120-150 km wavelength are indicative of internal tides, as noted by
513 Dufau et al. (2016); Savage et al., (2017), and others. In addition to the internal tide peaks, the
514 general higher spectral energy in the altimetry data at wavelengths < 200 km has been proposed to
515 be due to high-frequency internal gravity waves (eg Richman et al., 2012, Savage et al., 2017), but
516 may also include altimetric errors from surface waves and instrument noise (Dibarboure et al., 2014).
517 We will investigate the high-frequency contribution to the altimetric SSH spectra in the next section.

518 **5.2 Contributions from high-frequency dynamics including internal tides**

519 To investigate the contribution of the high-frequency SSH variations, we include an analysis of the
520 meridional SSH spectra from a small region east of the Solomon Sea in the SW Pacific. This spectral
521 analysis is derived from the 1/36° model with high-frequency atmospheric forcing and instantaneous
522 snapshots saved once per hour during a 3 month period, and run in the two configurations, with and
523 without tides (see section 2). The model has been validated and analysed (Djath et al., 2014), and a
524 companion paper will address the model with tides more fully (Tchilibou et al., 2018). Here we
525 consider specifically the impact of the different high-frequency tides and non-tidal signals on the
526 meridional SSH spectra.

527 The internal tide can be broken down into a coherent component that is predictable and can be
528 separated with harmonic and modal analysis, and an incoherent component that varies over time,
529 due to changing stratification (Zaron, 2017) or interaction with the mesoscale ocean circulation
530 (Ponte and Klein, 2015). The coherent baroclinic (internal) tide and the barotropic tide are calculated
531 in our study using a harmonic and modal decomposition (Nugroho, 2017) which separates the
532 barotropic mode and 9 internal tide modes, and provides a more stable energy repartition between
533 the baroclinic and barotropic components (F. Lyard, Personal Communication). Previous studies have
534 addressed the internal tide and high-frequency components in the tropics by careful filtering of a
535 model with tides (e.g. Richman et al., 2012; Savage et al., 2017). Aside from the issues of artifacts
536 introduced by the tidal filtering, it is often tricky to cleanly separate the spectral contributions
537 coming from the mesoscale ocean circulation and the incoherent component of the internal tides.
538 The advantage of using our two-model configuration is that we can specifically calculate the high-
539 frequency non-tidal components of the SSH spectra from the first model, and the component due to
540 the interaction of the internal tide and the model's eddy-current turbulence with the second model.

541 Fig.9 shows the geographical distribution of the standard deviation of SSH for the model including
542 the tidal forcing, for the low frequency (> 48 hr) component of the ocean (mesoscale) dynamics and
543 for the high frequency component (< 48 hr) due mainly to internal waves and internal tides. The large
544 mesoscale variability (up to 6 cm) east of the Solomon Sea in Fig. 9a is similar to the model without
545 tides (not shown), and well documented as current instability from the SECC-SEC current system (Qiu
546 and Chen, 2004). It is notable that the high frequency variability from the model with tides in Fig. 9b
547 is as high as the mesoscale variability, especially in the Solomon Sea, and comes mainly from the M2
548 baroclinic tide. We note that the M2 barotropic tide amplitude within the Solomon Sea is relatively
549 weak (not shown), and the largest internal tide amplitudes are close to their generation sites,
550 particularly where the barotropic tide interacts with the northern and southern Solomon Islands and
551 the southeastern Papua New Guinea (PNG) extremities (Tchilibou et al., 2018). For the model
552 without tides, the high frequency variability due to the atmospherically forced internal gravity waves
553 is very low (~1 cm) compared to the model with tides, and shows a relatively uniform distribution
554 (not shown).

555 The region used for our spectral analysis [2-13°S; 163-165°E; Fig. 9b] is outside the Solomon Sea, with
556 its strong regional circulation delimited by the islands and bathymetric gradients, and is more
557 representative of the open Pacific Ocean conditions analysed in the previous sections. The latitude
558 band from 2°S-13°S lies mostly the equatorial band defined in our previous analyses, and it is mainly
559 representative of the SECC region (Fig.3).

560 The meridional SSH spectra from the $1/36^\circ$ model run with no tides (R36h) with hourly outputs is
561 shown in Fig. 10 (in green). The SSH from this version with no tides but averaged over 5 days is also
562 shown (in orange), i.e., with equivalent temporal sampling to our $1/12^\circ$ model analysis. The
563 difference between these curves represents the non-tidal high-frequency component of the
564 circulation (< 10 days) due to rapid tropical waves and internal gravity waves forced by the
565 atmospheric forcing and current-bathymetric interactions. Also shown is the spectrum calculated at
566 the same location from our open-ocean G12d5 $1/12^\circ$ model (in cyan) with similar spectral slope to
567 the 5-day averaged version of our regional R36h $1/36^\circ$ model, though with slightly lower energy at
568 scales less than 70 km wavelength as expected, but also in the 180 to 600 km wavelength band. So
569 the $1/36^\circ$ model with no tides, when filtered to remove the high-frequency forcing, is quite close to
570 the $1/12^\circ$ model in this equatorial band. The main point is that the additional high-frequency
571 dynamics in R36h increase the spectral SSH power from 300 km down to the smallest scales from 0.4
572 cm^2 to 0.5 cm^2 , and reduce the spectral slope calculated in the fixed 70-250 km range from k^{-5} with
573 the 5-day average (in orange), to k^{-4} for the full model with no tides (in green).

574 The $1/36^\circ$ model with tides (R36Th) is also shown in blue, but with the barotropic tide removed. The
575 additional meridional SSH spectral power is due both to the coherent and incoherent internal tides,
576 with a large increase in variance up to 300 km wavelength from 0.5 cm^2 for R36h to 2.8 cm^2 for
577 R36Th. So, the main contributors to the high wavenumber SSH spectral power are from the baroclinic
578 tides compared to atmospherically-forced high frequency dynamics (green curve). To illustrate the
579 respective part of coherent and incoherent baroclinic tides, the coherent baroclinic tide signature
580 based on the nine tidal constituents summed over the first 9 internal modes is calculated, and this
581 signal is added to the model without tides (purple curve). The coherent baroclinic tides explain most
582 of the tidal signature in the 300-30 km wavelength range, and the difference with the raw signal
583 (blue curve) exhibits the signature of incoherent tides. The contribution of the incoherent
584 component increases significantly at scales smaller than 30 km and explain 30 % of the SSH variance.
585 The most energetic coherent internal tide component comes from the M2 tide, and the large
586 increase in amplitude centered around 120-140 km wavelength corresponds with the first baroclinic
587 mode (not shown). The other peaks around 70 km, and 40 km could be due to higher modes, and
588 similar peaks are found in the tidal analysis of MITGCM model data by Savage et al (2017) in the
589 central equatorial Pacific. At the main M2 internal tide wavelengths, the incoherent internal tide has
590 1.6 times the SSH energy of the coherent tide, indicating that even at the main internal tide
591 wavelengths, the incoherent internal tide is energetic.

592 We note that at wavelengths from 70-250 km used in the global altimetry spectral analysis, this $1/36^\circ$
593 model with the full tidal and high-frequency forcing has a flat spectral peak of around $k^{-1.5}$, quite
594 similar to the analysis of alongtrack spectral from Jason-2 (in dashed black) and Saral (in solid black),
595 in the same region but over the longer 2013-2014 period. We note that the barotropic tide has also
596 been removed from the altimetric data, using the same global tide atlas applied at the open
597 boundary conditions for our regional model (FES2014, Lyard et al., 2018). If we use the “mesoscale”
598 range defined for the global model analysis in the equatorial band over 100-600 km wavelength, we
599 still have a weak spectral slope of k^{-2} for both the model with tides and altimetry. Jason-2 has a
600 higher noise level than Saral at scales less than 30 km wavelength (Dufau et al., 2016); the small
601 differences in spectral energy between Jason-2 and Saral over wavelengths from 150 to 450 km may
602 be influenced by the different repetitive cycles of the very few tracks available (1 track for Jason-2
603 and 3 tracks for SARAL/AltiKA) between both missions, and their slightly different track positions.

604 This regional analysis provides a number of key results. The high-frequency, high-resolution regional
605 model confirms our open ocean $1/12^\circ$ analysis. The dynamics at scales > 10 days, with no tidal
606 forcing, give rise to SSH spectral slopes from 70-250 km of around k^{-5} in this equatorial band in
607 accordance with the G12d5 simulation. Note that it differs from the k^{-4} slope typical of the equatorial
608 region discussed above. It reflects modulation associated with low frequency variability. This 3 month
609 period corresponds with an El Niña event characterized by intense mesoscale activity in this region of
610 the South West Pacific (Gourdeau et al., 2014). Including the high-frequency but non-tidal forcing
611 increases the smaller-scale energy, and flattens the SSH spectra with slopes of around k^{-4} . This non-
612 tidal high-frequency (< 10 -day) component increases the SSH spectral energy out to scales of 200 km
613 wavelength, suggesting a dominance of rapid small-scale eddy variability of internal gravity waves
614 (Farrar and Durland, 2012; Garrett and Munk, 1975). But the higher frequency atmospheric forcing
615 and ocean instabilities alone cannot explain the very flat altimetric spectral slopes in this equatorial
616 region.

617 When coherent and incoherent internal tides are included, the spectral slope in the 70-250 km
618 wavelength band becomes very close to that observed with altimetric spectra. This confirms the
619 recent results presented by Savage et al. (2017) for a small box in the eastern tropics, and previously
620 proposed by Richman et al. (2012) and Dufau et al. (2016). The separation of the coherent M2
621 internal tide demonstrates that it clearly contributes SSH energy in the 50-300 km wavelength band,
622 but the incoherent tide, and its cascade of energy into the supertidal frequencies, is the dominant
623 signal at scales less than 50 km. The incoherent and coherent internal tides have similar energy
624 partitioning within the 50-300 km wavelength band.

625

626 **6. Discussion and Conclusion**

627 The processes that could contribute to the flat Sea Surface Height (SSH) wavenumber spectral slopes
628 observed in the tropics by satellite altimetry have been examined in the tropical Pacific. This study
629 has used two complementary approaches to better understand how the equatorial and off-
630 equatorial dynamics impact on the SSH wavenumber spectra. In the first part of this study, we have
631 concentrated on the low-frequency (> 10 days) internal tropical dynamics to better understand how
632 the complex zonal current system and dominant linear tropical waves affect the mainly meridional
633 altimetric SSH wavenumber spectra. In the second part of the study, we have used a high-frequency,
634 high-resolution regional modeling configuration, with and without tides, to explore the high-
635 frequency contributions to the meridional SSH wavenumber spectra.

636 Our $1/12^\circ$, 5-day averaged model confirms the results from previous modeling studies that at
637 seasonal to interannual time scales the most energetic large-scale structures tends to be anisotropic
638 and governed by linear dynamics. At intraseasonal frequencies and in the tropical “mesoscale” band
639 at scales less than 600 km wavelength, one major question was how the cascade of energy is affected
640 by the expected high level of anisotropy and the weak non-linear regimes. Within the “mesoscale”
641 range, the EKE wavenumber spectra is isotropic in the off-equatorial regions between 10° and 20° ,
642 and it is more anisotropic in the equatorial region between 10°N - 10°S , with higher level of energy for
643 the meridional EKE spectrum than for the zonal one that reveals the energetic meridional
644 perturbations due to instabilities of the larger-scale zonal currents.

645 In the off-equatorial range, EKE peaks at around 300 km wavelength, and the steep EKE decrease at
646 smaller wavelength is characterized by spectral slopes between k^{-2} and k^{-3} , which lie between the
647 regimes of SQG and QG turbulence. These weakly nonlinear off-equatorial regions thus have a similar
648 structure to the non-linear mid-latitudes within the range from 100-250 km. In the equatorial band
649 from 10°S - 10°N , the total EKE is more energetic than the off-equatorial region, and the spectral
650 cascade extends over a large wavenumber range, from 100 to 600 km. Again, the EKE spectral slope
651 within this range approaches k^{-3} , consistent with QG dynamics, even though there is a strong
652 ageostrophic component here. Using the fixed wavelength (70-250 km) band to estimate
653 “mesoscale” spectral slope leads to a slight reduction in the low-frequency spectral slope estimate,
654 but without a drastic modification. When geostrophic velocities are used to calculate EKE rather than
655 the total surface flow, there is similar spectral energy in the off-equatorial regions at longer
656 wavelengths. In the equatorial band 10°N - 10°S , the ageostrophy is more evident with a more marked
657 change in spectral slope based on geostrophic velocities and the beta-approximation at the equator.
658 At large scales in the equatorial band, the ageostrophic equatorial currents are more active, related
659 to the energetic zonal currents. In all regions, at wavelengths shorter than 200 km, the geostrophic
660 spectra become more energetic and the small-scale ageostrophic components are counteracting the
661 balanced geostrophic flow, as found at mid-latitudes (Klein et al., 2008). This gives a slightly flatter
662 spectral slope over the 70-250 km wavelength, but the regime remains between k^{-2} and k^{-3} in the off-
663 equatorial region, approaching k^{-2} (and k^{-4} in SSH) in the equatorial band. So using SSH and
664 geostrophic currents slightly flattens the wavenumber spectra, but cannot explain alone the very flat
665 altimetric SSH spectra.

666 The choice of regional box size and filtering options also impacts on the spectra. Previous global
667 altimetric studies have calculated alongtrack SSH wavenumber spectra in $10^{\circ}\times 10^{\circ}$ boxes, and with
668 varying segment lengths (512 km for Dufau et al., 2016; around 1000 km for Xu and Fu, 2011,
669 Chassignet et al., 2017, etc), and with different tapering or filtering applied (see section 3). In the
670 equatorial band where the EKE peak extends out to 600 km wavelength, it is important to have
671 segment sizes and filtering that preserve this peak and shorter scales. The combined effects of a 10%
672 cosine taper and the short segment lengths leads to a much flatter altimetric SSH spectra, reaching k^{-1}
673 in the Dufau et al (2016) study. We find that the double periodic spectra, the hanning and tukey
674 50% taper filter all give similar results in the tropics, but it is necessary to extend the box size to a
675 minimum of 15° to 20° in segment length or box size in the equatorial band. In the off-equatorial
676 band, these filtering options with a 10° segment length or box size are sufficient. Even with the
677 preferred pre-processing for the altimetric data, and larger segment lengths in our analyses, the
678 altimetric SSH spectra remain quite flat (k^{-2} in the off-equatorial zone, $k^{-1.3}$ in the equatorial band),
679 and do not reflect the steeper, more turbulent spectral slopes predicted by the model.

680 The regional high-resolution models with both high-frequency atmospheric and tidal forcing and
681 high-frequency hourly outputs provide the last pieces of the puzzle. In contrast to previous results
682 based on global ocean models with tidal forcing (Richman et al., 2012; Savage et al., 2017), this 2-
683 model configuration with and without tides, has the same atmospheric and boundary forcing, which
684 allows us to clearly separate the internal tide signals from the high frequency dynamical component.
685 Even though only a small region of the tropical Pacific is available for this analysis, the regional model
686 and the global $1/12^{\circ}$ model show similar QG spectral slopes when they are compared over the same
687 domain and with 5-day averaged data. Using hourly data and no tides increases the SSH spectral
688 power at scales smaller than 200 km, possibly due to internal gravity waves in the tropics (Farrar and

689 Durland, 2012; Garrett and Munk, 1975). We note that Rocha et al. (2016) found a similar increase in
690 their detided alongtrack model runs in Drake Passage, but at scales less than 40 km wavelength, far
691 below the noise level of our present altimeter constellation. In the tropics, this contribution of high-
692 frequency non-tidal SSH signals out to 200 km wavelength will also impact on today's alongtrack
693 altimeter constellation, whose noise levels block ocean signals at scales less than 70 km for Jason
694 class satellites, and 30-50 km for Saral and Sentinel-3 SAR altimeters (Dufau et al., 2016). So non-tidal
695 internal gravity waves will partially contribute to the higher small-scale SSH variance and flatter
696 spectral slopes in today's altimetric SSH data.

697 The regional model with tides shows the very important contribution of internal tides to the flat SSH
698 slopes in the tropics. We have separated out the predictive part of the barotropic tide and internal
699 tides, since open ocean barotropic tides are well corrected for in altimetric data today (Lyard et al.,
700 2018; Stammer et al., 2014), and corrections are becoming available for the coherent part of the
701 internal tide (Ray and Zaron, 2016). In this open ocean tropical region east of the Solomon Sea, when
702 coherent and incoherent internal tides are included, the spectral slope in the 70-250 km wavelength
703 band becomes very close to that observed with altimetric spectra. This confirms the recent results
704 presented by Savage et al. (2017) for a small box in the eastern tropics, and previously proposed by
705 Richman et al. (2012) and Dufau et al. (2016). The separation of the coherent M2 internal tide
706 demonstrates that it clearly contributes significant SSH energy in the 50-300 km wavelength band,
707 but around the main internal tide wavelengths, there is a strong signature of M2 incoherent internal
708 tide. The incoherent tide, and its cascade of energy into the supertidal frequencies, is the dominant
709 signal at scales less than 50 km. This strong incoherent internal tide is consistent with recent studies
710 that suggest that internal tides interacting with energetic zonal jets can generate a predominate
711 incoherent internal tide (Ponte and Klein, 2015), and may explain the reduction of the coherent
712 internal tides in the equatorial band in global models (Shriver et al., 2014) and altimetric analyses
713 (Ray and Zaron, 2016). Our model highlights that the internal tide signal is strong in this equatorial
714 region, and the incoherent tide accounts for 35% of the SSH spectral power in the 50-300 km
715 wavelength band, and is not predictable.

716 These results have important consequences for the analyses of alongtrack altimetric data today, and
717 for the future high-resolution swath missions such as SWOT. Today's constellation of satellite
718 altimeters have their alongtrack data filtered to remove noise at scales less than 70 km for all
719 missions (Dibarboure et al., 2014; Dufau et al., 2016), and these data are now being used with no
720 internal tide correction in the global gridded altimetry maps of SSH and geostrophic currents. The
721 imprint of these internal tides is evident in the alongtrack data (see Fig. 1b from Dufau et al., 2016)
722 but is also present in the gridded maps (R. Ray, personal communication). In the future, a coherent
723 internal tide correction may be applied to the alongtrack data based on Ray and Zaron (2016), to
724 reduce some of this non-balanced signal. It is particularly important to remove the unbalanced
725 internal wave signals from SSH before calculating geostrophic currents. But it is clear that the
726 incoherent internal tide and internal gravity waves reach scales of 200 km in the tropics, and their
727 signature in SSH remains a big issue for detecting balanced internal ocean currents from alongtrack
728 altimetry and the future SWOT wide-swath altimeter mission. Removing this signal to detect purely
729 balanced motions will be challenging, since filtering over 200 km removes much of the small-scale
730 ocean dynamics of interest in the tropics. On the other hand, there will also be a great opportunity to
731 investigate the interaction of the internal tide and ocean dynamics in the tropics in the future, with
732 both models and fine-scale altimetric observations.

733

734 **Acknowledgments**

735 The authors wish to acknowledge Ssalto/Duacs AVISO who produced the altimeter products, with
736 support from CNES (<http://www.aviso.altimetry.fr/duacs/>). The authors would like to thank the
737 DRAKKAR team for providing them with the high resolution global ocean simulation, and especially
738 J.M. Molines for his support. This work benefited from discussions with J. Jouanno, F. Marin, Y. Morel
739 from LEGOS. We particularly thank J. Verron (IGE), C. Menesguen (LOPS), and X. Capet (LOCEAN) for
740 their time, and their fruitful comments. M. Tchilibou is funded by Université de Toulouse 3. L.
741 Gourdeau, G. Sérazin are funded by IRD; R. Morrow is funded by CNAP, and B. Djath was funded by
742 CNES. This work is a contribution to the joint CNES/NASA SWOT project “SWOT in the tropics” and is
743 supported by the French TOSCA programme.

949

950 Figure 1: a) Spatial distribution of altimetric alongtrack SSH wavenumber spectral slope calculated in
951 the fixed 70-250 km mesoscale range (from Xu and Fu, 2011; their Fig. 2). b) Latitudinal dependence
952 of the altimetric SSH alongtrack wavenumber spectra in the Atlantic Ocean (from Dufau et al., 2016;
953 their Fig. 3). The colors of the spectra refer to the geographical boxes where alongtrack data were
954 averaged on the right.

955 Figure 2: Sensitivity experiments for different spectral processing techniques applied to meridional
956 SSH wavenumber spectra representative of the equatorial region. a) SSH wavenumber spectra using
957 a Tukey 0.1 window (blue) and a Tukey 0.5 window (red) depending on segment lengths: 5° (dots),
958 10° (dash), 20° (line). b) SSH wavenumber spectra using different windowing over a 20° segment
959 length: Tukey 0.1 window (Tk01, blue), Tukey 0.5 window (Tk05, red), Hanning window (Han, green).
960 The double periodic method (Dbp, black) is also tested. For reference k^{-1} and k^{-5} curves are plotted.
961 Units : cm^2/cpkm

962 Figure 3: Snapshot of relative vorticity of the $1/12^\circ$ G12d5 simulation. unit in $1.E5 \text{ s}^{-1}$. The yellow lines
963 delineate the equatorial and off-equatorial regions. The dashed lines delineate square boxes for the
964 different regions to compute wavenumber spectra. The black arrows illustrate the main zonal
965 tropical currents (SEC: South Equatorial Current, SECC: South Equatorial CounterCurrent, NECC:
966 North Equatorial CounterCurrent, NEC: North Equatorial Current, STCC: SubTropical CounterCurrent,
967 HLCC: Hawaii Lee Counter Current).

968 Figure 4: a) latitudinal distribution of the EKE Frequency power spectra computed at each model grid
969 point of the G12d5 simulation, and averaged in longitude. The black line is the critical period from Lin
970 et al. (2008). b) longitudinal distribution of the EKE Frequency power spectra computed at each
971 model grid point of the G12d5 simulation, and averaged between 20°S - 20°N . Units are in \log_{10} of
972 $\text{cm}^2/\text{s}^2/\text{cpday}$.

973 Figure 5: Zonal wavenumber-frequency EKE spectra averaged over a) 10°N - 20°N region, b) 10°S - 10°N
974 region, and c) 10°S - 20°S region. d) Meridional wavenumber-frequency EKE spectra covering 20°S -
975 20°N averaged over the 120°W - 150°W region. Superimposed on a) and c) are the theoretical
976 dispersion curves for the first mode baroclinic waves. Superimposed on b) are the theoretical
977 dispersion curves for the first 3 baroclinic wave modes, and the Kelvin wave mode. Units are in \log_{10}
978 of $\text{cm}^2/\text{s}^2/\text{cpday}/\text{cpkm}$.

979 Figure 6: Zonal wavenumber EKE spectra averaged over the equatorial (orange line), and off-
980 equatorial latitude bands (north: green; south: blue). Units are in $\text{cm}^2/\text{s}^2/\text{cpkm}$.

981 Figure 7: 1D zonal (orange), meridional (green); and 2D isotropic (blue) EKE wavenumber spectra
982 averaged over a) 10°N - 20°N , b) 10°S - 10°N , and c) 10°S - 20°S regions. The isotropic geostrophic EKE
983 wavenumber spectra is also shown (EKEg, blue dash line). The vertical green dash lines delineate the
984 fixed 70-250 km mesoscale range. For reference, k^{-2} and k^{-3} curves are plotted (black lines). Units are
985 in $\text{cm}^2/\text{s}^2/\text{cpkm}$.

986 Figure 8: Meridional SSH wavenumber spectra averaged over the equatorial (orange), and off-
987 equatorial latitude bands (north: green, south:blue) for the G12d5 simulation (line). Topex-Poseidon
988 along track altimetric SSH wavenumber spectra are averaged over the same latitude bands (dash).
989 Units are in cm^2/cpkm .

990 Figure 9: SSH variability of the $1/36^\circ$ regional model with explicit tides (R36Th) over the 3 month
991 simulation for a) the mesoscale signal, and b) the internal waves and internal tides defined by a 48 hr
992 cutoff period. Units in cm^2 . The SARAL/AltiKA (black line) and Jason-2 (dash line) tracks used to
993 compute the altimetric spectra in Fig. 10 are superimposed.

994 Figure 10: Meridional SSH wavenumber spectra averaged over 163°E - 165°E for the hourly outputs of
995 the $1/36^\circ$ resolution regional model without tides (R36h, green), and 5 day averaged outputs (R36d5,
996 orange). Meridional SSH spectra of the G12d5 simulation is in cyan. SSH meridional wavenumber
997 spectra for the hourly outputs of the $1/36^\circ$ regional model with explicit tides once the barotropic
998 tides has been removed (R36Th-BT, in blue). The spectrum of the coherent baroclinic tides has been
999 added to the spectrum of the model without tides (R36h+BC, purple), the contribution of the only
1000 M2 coherent baroclinic tide is in red (R36h+M2BC). The difference between the blue and purple
1001 curves corresponds with the incoherent internal tides. The corresponding along track SSH altimetric
1002 spectra for SARAL/AltiKa (line) and Jason-2 (dash) are in black. Units are in cm^2/cpkm .
