

Interactive comment on “Could the mesoscale eddies be reproduced and predicted in the northern south China sea: case studies” by Dazhi Xu et al.

Anonymous Referee #2

Received and published: 16 September 2018

The motion and transport of mesoscale eddies have been intensively studied with the altimeter data. In contrast, the simulations are relatively very few, although they are more useful for prediction and applications. As the simulations in this paper are quite well, I have a few minor comments on results. My major concerns are how to improve the writing skill of the paper to make it more comprehensible and valuable for readers. In final, the result is interesting and valuable, but some minor revisions are required before publication.

1. In this paper, both amplitude and intensity are used. In general, eddy amplitude was common used in previous studies (e.g., Chelton et al., 2011). I suggest authors use

C1

amplitude other than intensity in the paper.

2. The motivation of study may be stressed in a more comprehensive way for board readers, if the authors include the previous knowledge on evolution and propagation of oceanic eddies from altimeter data. The motion of mesoscale eddies would be a straight line, if eddies freely propagate in open ocean. However, most of eddies may have interaction with topography (costal and islands), strong currents (e.g., western boundary current), eddies during their lifetime. The motion of eddy will be modified and even split when approaching an island (Yang et al., 2017). It is also recognized that western boundary is graveyard of eddies (Zhai et al., 2010). The dynamical processes such as splitting and/or merging of eddies can also make termination and/or genesis of eddies in open ocean (Li et al., 2016). Thus the dynamical processes make that the prediction of eddy motion is a challenge for ocean simulation.

3. The result is useful that generation, evolution and propagation paths of AE1 and AE2 can be well reproduced and forecasted when their amplitude >8 cm. I have two comments on this point. Firstly, authors should clearly point out what “their amplitude” means, observed one or simulated one. Secondly, the values in tables should be clearly consist with this result.

4. Moreover, amplitude is good criterion, a dimensionless one might be better, which makes the result more valuable. This could be achieved if the authors may go one step further. As we know that mesoscale eddies are nonlinear compare with linear Rossby waves (Chelton et al., 2011), they are quite different, e.g., for propagation speed. It is hypothesized that the advective nonlinearity parameter might be presumably important, and authors may use it as an additional criterion. The advective nonlinearity parameter is defined as the nondimensional ratio U/c , where U is the maximum rotational speed and c is the translation speed of the eddy. A value of $U/c > 1$ implies theoretically that there is trapped fluid within the eddy interior that is advected with the eddy as the eddy translates, which is a fundamental distinction between linear waves and nonlinear eddies. The authors can check their results: what U/c exactly is in their simulations.
