Abstract

11

12 Great progress has been made in understanding the mesoscale eddies and their role on
13 the large-scale structure and circulation of the oceans. However, many questions still
14 remain to be resolved, especially with regard to the reproductivity and predictability of
15 mesoscale eddies. In this study, the reproductivity and predictability of mesoscale
16 eddies in the Northern SCS (NSCS), a region with strong eddy activity, are investigated
17 with a focus on two typical anticyclonic eddies (AE1 and AE2) based on a HYCOM-
18 EnOI Assimilated System. The comparisons of assimilated results and observations
19 suggest that generation, evolution and propagation paths of AE1 and AE2 can be well
20 reproduced and forecasted when the observed amplitude >8 cm (or the advective
21 nonlinearity parameter U/c greater than 2), although their forcing mechanisms are quite
22 different. However, when their amplitudes are less than 8 cm, the generation and decay
23 of these two mesoscale eddies cannot be well reproduced and predicted by the system.
24 This result suggests, in addition to dynamical mechanisms, the spatial resolution of
25 assimilation observation data and numerical models must be taken into account in
26 reproducing and predicting mesoscale eddies in the NSCS.

29 Predictability

30 **1. Introduction**

31 Equivalent to the synoptic variability of the atmosphere, ocean mesoscale eddies
32 are often described as the “weather” of the ocean, with typical spatial scales of ~100
33 km and time scales of a month (Wang et al., 1996; Liu et al., 2001; Chelton et al., 2011).
34 The mesoscale eddy is characterized by temperature and salinity anomalies with
35 associated flow anomalies, exhibiting different properties to their surroundings, thus
36 allowing them to control the strength of mean currents and to transport heat, salt, and
37 biogeochemical tracers around the ocean. The motion of mesoscale eddies would be a
38 straight line, if eddies freely propagate in open ocean. However, most of eddies may
39 have interaction with topography, strong currents (western boundary current), eddies
40 during their lifetime. The motion of eddy will be modified and even split when
41 approaching an island (Yang et al., 2017). It is also recognized that western boundary
42 is graveyard of eddies (Zhai et al., 2010). The dynamical processes such as splitting
43 and/or merging of eddies can also make termination and/or genesis of eddies in open
44 ocean (Li et al., 2016). Thus, the dynamical processes make that the prediction of eddy
45 motion is a challenge for ocean simulation. Although today, the beauty and complexity,
46 the scales resolved, the eddy energy and tracking and the effects on atmosphere of these
47 mesoscale features can be seen by viewing high resolution satellite images or numerical
48 model simulations (Yang et al., 2000; Fu et al., 2010; Morrow and Le Traon, 2012;
49 Frenger et al., 2013), the operational forecasts of the mesoscale eddy still pose a big
50 challenge because of its complicated dynamical mechanisms and high nonlinearity
51 (Woodham et al., 2015; Treguier et al., 2017; Vos et al., 2018). A recent example is the

52 explosion of the Deepwater Horizon drilling platform in the northern Gulf of Mexico
53 in 2010 where an accurate prediction of the position and propagation of the Loop
54 Current eddy was essential in determining if the spilled oil would be advected to the
55 Atlantic Ocean or still remain within the Gulf (Treguier et al., 2017).

56 Similar to Gulf of Mexico, the South China Sea (SCS) is also a large semi-closed
57 marginal sea in the northwest Pacific, connecting to the western Pacific through the
58 Luzon Strait (Fig. 1). Forced by seasonal monsoon winds, the intrusion of Kuroshio
59 Current (KC), the Rossby waves and the complex topography, the SCS, especially the
60 Northern SCS (NSCS) exhibits significant mesoscale eddy activity (Fig. 2). Many
61 studies have tried to investigate mesoscale eddies in the NSCS (Wang et al., 2003; Jia
62 et al., 2005; Wang et al., 2008). Based on the potential vorticity conservation equation
63 and in-situ survey data, Yuan and Wang (1986) pointed out that the bottom topography
64 forcing might be the primary factor for the formation of anticyclonic eddies in the
65 northeast of Dongsha Islands (DIs). Using survey CTD data in September 1994, Li et
66 al. (1998) recorded evidence of anticyclonic eddies in the NSCS and suggested these
67 anticyclonic eddies are probably shed from the KC. Investigations by Wu et al. (2007)
68 showed that westward propagating eddies in the NSCS originate near the Luzon Strait
69 rather than coming from the western Pacific. Based on the altimeter, the trajectory of
70 drift and the hydrological observations data, Wang et al. (2008) studied the evolution
71 and migration of two anticyclonic eddies in the NSCS during winter of 2003/2004. As
72 they described, the AE1 generated by interaction of the unstable rotating fluid with the
73 sharp topography of DIs firstly appeared near DIs on the 10th of December 2003 (see

74 Fig. 3). Then it began to move southwestward with its amplitude decreasing gradually.
75 During the movement of AE1, another anticyclonic eddy (AE2) was shed and
76 developed from the loop current of Kuroshio near the Luzon Strait on the 14th of January
77 2004. The amplitude of AE2 was then increased when it propagated southwestward
78 (Fig. 3d-3f). About five weeks later, AE2 reached its maximum in amplitude and then
79 lasted around three weeks in its mature state. During its decay phase, AE2 moved
80 southwestward quickly with its amplitude decreasing, and finally disappeared at the
81 location of 114°E, 18°N on the 7th of April 2004. Meanwhile, AE1 continued moving
82 to southwest and eventually disappeared southeast of Hainan. In addition to physical
83 characteristics, the phytoplankton community at these two eddies have also been
84 studied by Huang et al. (2010). These studies improved our understanding of activities
85 of mesoscale eddy and its possible dynamical mechanisms in the NSCS.

86 Despite the activities and its possible dynamical mechanisms of mesoscale eddies
87 in the NSCS having received much attention in past decades, studies on the
88 reproductivity and predictability of mesoscale eddies in the NSCS are still rare. As
89 mentioned above, mesoscale eddies are not only related to complicated dynamical
90 mechanisms but also involve strong nonlinear processes (Oey et al., 2005); they are not
91 a deterministic response to atmospheric forcing. The quality of mesoscale eddies
92 forecasting will depend primarily on the quality of the initial conditions. Ocean data
93 assimilation, which combines observations with the numerical model, can provide more
94 realistic initial conditions and thus is essential for the prediction of mesoscale eddies.
95 As shown by previous studies, after assimilating altimeter data into ocean models, the

96 ocean currents in the southern SCS (Xiao et al., 2006) and the realism of three largest
97 eddies in the SCS appear during Typhoon Rammasun (Xie et al., 2018) have been
98 improved. Furthermore, some studies show that the ocean model includes tides or
99 assimilated altimeter data with reasonable MDT, can provide more realistic initial
100 conditions (Xie et al., 2011; Xu et al., 2012). The above studies show that the mesoscale
101 eddies in the SCS are reproducible, but about the predictability of mesoscale eddies is
102 rare. In this study, we assessed the reproduction and predictability of two typical
103 anticyclonic eddies (Wang et al., 2008), owing to be represented different generation
104 mechanisms and survive long enough to be useful, in the NSCS with focus on their
105 generation, evolution and decay processes by a series of numerical experiments based
106 on a Chinese Shelf/Coastal Seas Assimilation System (CSCASS; Li, 2009; Li et al.,
107 2010; Zhu, 2011) along with the observation data from surface drifter trajectory and
108 satellite remote sensing.

109 **2. Datasets and Methodologies**

110 **2.1 Datasets**

111 In this study, the altimetric data between 2003-2004, which includes along-track
112 SLA, totally 29 passes (about 9300 points) over the domain of CSCS was selected.
113 Considering the noise of SLA measurement in the shallow seas, data for the shallow
114 areas with depth<400 m was excluded. In order to verify, the merged SLA based on
115 Jason-1, TOPEX/Poseidon, ERS-2 and ENVISAT (Ducet et al., 2000) provided by
116 Archiving, Validation and Interpretation of Satellites Oceanographic data (AVISO) at

117 Centre Localization Satellite (CLS, <ftp://ftp.aviso.oceanobs.com/global/nrt/>) with $1/4^\circ$
118 $\times 1/4^\circ$ resolution and weekly average are used. In addition, because the SLA present
119 only the anomalies relative to a time-mean sea level field, thus a new mean dynamic
120 topography (nMDT), which has been corrected using iterative method by Xu et al.
121 (2012) was used to calculate the realistic sea level in this study.

122 In addition to SLA datasets, the daily OISST from the National Oceanic and
123 Atmospheric Administration's (NOAA) National Climatic Data Center
124 (<ftp://eclipse.ncdc.noaa.gov/pub/OI-daily-v2/NetCDF/>), which was merged by an
125 optimum interpolation method (Reynolds et al., 2007) based on the Infrared SST
126 collected by the Advanced Very High Resolution Radiometer sensors on the NOAA
127 Polar Orbiting Environmental Satellite and SST from Advanced Microwave Scanning
128 Radiometer for the Earth Observing System, are also used. The daily OISST's biases
129 were fixed using in situ data from ships and buoys. The dataset between 2003 and 2004
130 was used in this study, with a spatial resolution of $1/4^\circ \times 1/4^\circ$. In addition, the surface
131 drifting buoy data from the World Ocean Circulation Experiment (WOCE,
132 <ftp://ftp.aoml.noaa.gov/pub/phod/buoydata/>) are also used. Three drifters were
133 designed to drift at the surface within the upper 15 m and tracked by the ARGOS
134 satellite system. Positions of the drifters were smoothed using a Gaussian-filter scale of
135 24 h to eliminate tidal and inertial currents, and were subsampled at 6 h intervals
136 (Hamilton et al., 1999).

137 **2.2 Method of identify the mesoscale eddies**

138 Similar to the standard of Cheng et al. (2005) and Chelton et al. (2011), we identify

139 the mesoscale eddies in this study as follows: 1) there must be a closed contour on the
140 merged SLA; 2) there must be one maximum or minimum inside the area of the closed
141 contour for anticyclonic or cyclonic eddy; 3) the difference between the extremum and
142 the outermost closed SLA contour, that is, the amplitude of the mesoscale eddy, must
143 be greater than 2 cm; and 4) the spatial scale of the eddy should be 45-500 km. In
144 addition, the amplitude (A) of an eddy is defined here to be the magnitude of the
145 difference between the estimated basal height of the eddy boundary and the extremum
146 value of SSH within the eddy interior: $A=|h_{\text{ext}}-h_0|$.

147 **2.3 Ocean model**

148 We here used a three-dimensional hybrid coordinate ocean model (HYCOM;
149 Halliwell et al., 1998; 2000; Bleck, 2002; Halliwell, 2004; Chassignet et al., 2007) to
150 provide a dynamical interpolator of observation data in the assimilation system.
151 HYCOM is a primitive equation general ocean circulation model with vertical
152 coordinates: isopycnic coordinate in the open stratified ocean, the geopotential (or z)
153 coordinate in the weakly stratified upper ocean, and the terrain following sigma-
154 coordinate in shallow coastal regions.

155 In this study, HYCOM was implemented in the Chinese shelf/coastal seas with a
156 horizontal resolution of $1/12^\circ \times 1/12^\circ$, and in the remaining regions with $1/8^\circ \times 1/8^\circ$, the
157 model domain is from 0°N to 53°N and from 99°E to 143°E , the detail model domain
158 and grid can refer to the inset panel of Fig.1. The vertical water column from the sea
159 surface to the bottom was divided into 22 levels. The K-Profile Parameterization (KPP;
160 Large et al., 1994), which has proved to be an efficient mixing parameterization in many

161 oceanic circulation models, was used here. The bathymetry data of the model domain
162 were taken from the 2-Minute Gridded Global Relief Data (ETOPO2).

163 To adjust the model dynamics and achieve a perpetually repeating seasonal cycle
164 before applying the interannual atmospheric forcing, the model was initialized with
165 climatological temperature and salinity from the World Ocean Atlas 2001 (WOA01;
166 Boyer et al., 2005) and was driven by the Comprehensive Ocean-Atmosphere Data Set
167 (COADS; Woodruff et al., 1987) in the spin-up stage. After integrating ten model years
168 with climatological forcing, the model was forced by the European Center for Medium-
169 Range Weather Forecasts (ECMWF) 6-hourly reanalysis dataset (Uppala et al., 2005)
170 from 1997 to 2003. The wind velocity (10-m) components were converted to stresses
171 using a stability dependent drag coefficient from Kara et al. (2002). Thermal forcing
172 included air temperature, relative humidity and radiation (shortwave and longwave)
173 fluxes. Precipitation was also used as a surface forcing from Legates and Willmott
174 (1990). Surface latent and sensible heat fluxes were calculated using bulk formulae
175 (Han, 1984). Monthly river runoff was parameterized as a surface precipitation flux in
176 the ECS, the SCS and Luzon Strait (LS) from the river discharge stations of the Global
177 Runoff Data Centre (GRDC) (<http://www.bafg.de>), and scaled as in Dai et al. (2002).
178 Temperature, salinity and currents at the open boundaries were provided by an India-
179 Pacific domain HYCOM simulation at $1/4^\circ \times 1/4^\circ$ spatial resolution (Yan et al., 2007).
180 Surface temperature and salinity were relaxed to climate on a time scale of 100 days.
181 Both two-dimensional barotropic fields such as Sea Surface Height and barotropic
182 velocities, and three-dimensional baroclinic fields such as currents, temperature,

183 salinity and density were stored daily.

184 2.4 The assimilation scheme

185 The ensemble optimal interpolation scheme (EnOI; Oke et al., 2002), which is
186 regarded as a simplified implementation of the Ensemble Kalman Filter (EnKF), aims
187 at alleviating the computational burden of the EnKF by using stationary ensembles to
188 propagate the observed information to the model space. The data assimilation schemes
189 can be briefly written as (Oke et al., 2010):

$$190 \quad \vec{\psi}^a = \vec{\psi}^b + K(\vec{d} - H\vec{\psi}^b) \quad (1)$$

$$191 \quad K = P^b H^T [HP^b H^T + R]^{-1} \quad (2)$$

192 where $\vec{\psi}$ is the model state vectors including model temperature, layer thickness and
193 velocity; Superscripts a and b denote analysis and background, respectively; \vec{d} is
194 the measurement vector that consists of SST and SLA observations; K is the gain
195 matrix; and H is the measurement operator that transforms the model state to
196 observation space. P is the background error covariance and R is the measurement
197 error covariance. In EnOI, Eq. 2 can be expressed as:

$$198 \quad K = \alpha(\sigma \circ P^b)H^T [\alpha H(\sigma \circ P^b)H^T + R]^{-1} \quad (3)$$

199 where α is a scalar that can tune the magnitude of the analysis increment; σ is a
200 correlation function for localization; and P^b is the background error covariance which
201 can be estimated by

$$202 \quad P^b = A'A'^T / (n - 1) \quad (4)$$

203 In Eq. 4, n is the ensemble size, A' is the anomaly of the ensemble matrix, $A =$

204 $(\psi_1, \psi_2, \dots, \psi_N) \in \mathfrak{R}^{n \times N}$ ($\psi_i \in \mathfrak{R}^N (i = 1, \dots, n)$) is the ensemble members, N is the
205 dimension of the model state, representing usually the model variability at certain scales
206 by using a long-term model run or spin-up run. More detailed description and
207 evaluation of the CSCASS are in Li et al. (2010) and Xu et al. (2012).

208

209 **3. Results**

210 **3.1 The reproduction of anticyclonic eddies AE1 and AE2 in the NSCS**

211 In order to investigate whether the evolution and migration features of these two
212 eddies can be reproduced by the CSCASS or not, we firstly set up an assimilation
213 experiment named As_exp (see Fig. 4, black line) for AE1 and AE2. In this experiment,
214 the observed SST and SLA are both assimilated into CSCASS every 3 days. To meet
215 dynamic adjustment, the first assimilation was performed on the 27th of September 2003,
216 two months prior to the generation of AE1.

217 Base on the As_exp experiment output, we use the observations SLA to evaluate
218 the uncertainty of CSCASS in the research area. In this study, we calculated the weekly
219 mean RMS error (RMSE) of the As_exp /control experiments output and observations
220 for SLA. As the result indicates, the RMSE for the As_exp is between 6 cm to 14 cm,
221 while RMSE for the control is between 10 cm to 18 cm. This result suggested that data
222 assimilation improved effectively the SLA field and had a beneficial impact on model
223 results in this area.

224 In addition, we also use the Advective Nonlinearity Parameter U/c (ANP, Chelton
225 et al., 2011; Li et al., 2014; 2015; 2016; Wang et al., 2015) as a criterion to estimate the

226 eddy forecast ability of the CSCASS. As fig. 5 shows, when the ANP is greater than 2
227 (that is the amplitude greater than 8 cm) AE2 can be well reproduced by the CSCASS.

228 Besides, we also use the independent evaluation, Fig.6 compared the assimilating
229 results of AE1 with the observations both from the satellite remote sensing and drifter
230 buoys trajectories of number 22517, 22918 and 22610 between December 3rd 2003 and
231 February 18th 2004. From Fig. 6 and Table 1, we can see that the generation and
232 movement of AE1 can be well reproduced by the CSCASS, with the pink curves
233 (assimilation) match well with those of black (satellite observations) and dotted lines
234 (the trajectories of drifter buoys). In addition, the spatial pattern of AE1 can also be well
235 revealed by the CSCASS: the meridional and zonal radii of AE1 detected by the
236 assimilation are 163 km and 93 km, which are almost equal to that of observations (148
237 km and 79 km). The migration path of AE1 can also be well reproduced by the CSCASS
238 (see Fig. 6, black and pink line) until its amplitude decays to less than 8 cm. In addition
239 to AE1, the generation and evolution of AE2 are also evaluated. As shown Fig. 7, the
240 evolution and propagation pathway of AE2 (Fig. 7b-7j), e.g. moving northwestward
241 firstly and then southwestward, can generally be reproduced by the CSCASS, although
242 its initial location shows a slight southward bias in the simulation (Fig. 7a). Similar to
243 the results of AE1, discrepancies between model and observations become larger again
244 during the decay phase of AE2.

245 In general, the comparison of assimilation SLA with that of satellite observation
246 and the trajectories of drifter buoys suggested that the generation, development and the
247 propagation of AE1 and AE2 can be reproduced by the CSCASS when their observed

248 amplitude greater than 8 cm (or the ANP greater than 2). However, when their
249 amplitudes are relatively small, less than 8 cm, the features of these two mesoscale
250 eddies are not well reproduced by the CSCASS. This may be related to the value setting
251 of parameter α , the localization length scale, and insufficient spatial resolution of
252 assimilated SSH or the numerical model (Counillon and Bertino, 2009).

253 **3.2 The predictability of these anticyclonic eddies in the NSCS**

254 Since the generation, development and the propagation of AE1 and AE2 can be
255 well reproduced by the CSCASS when their amplitude > 8 cm (or the ANP greater than
256 2), as mentioned above, in this section we further use the CSCASS to investigate the
257 predictability of these two eddies. According to the generation, evolution and migration
258 of these two eddies, we designed six forecast experiments, hereafter referred to as Exp1
259 to Exp6 (see Fig.4) to investigate their predictability. The model's initial state prior to
260 each of the six forecast experiments is constrained by assimilating satellite SLA and
261 SST before. Based on the initial state, each experiment is run forward 30 days with the
262 forcing of 6-hourly wind, surface heat flux, and monthly mean river runoff, etc. The
263 first experiment, named Exp1, is applied on the 29th of November 2003, which tends to
264 study whether the generation of AE1 can be forecasted or not. Exp2 is implemented on
265 the 10th of December 2003 and is used to study whether the development and the
266 migration of AE1 can be forecasted. Exp3 is run based on the initial state on the 31th of
267 December 2003 and used to show whether the generation of AE2 and the continued
268 migration of AE1 can be forecasted. In order to investigate whether the continued
269 evolution of AE1 and AE2 can be forecasted, Exp4 is applied on the 21th of January

270 2004. Exp5, is setting up to reveal whether the attenuation of AE1 and the evolution of
271 AE2 can be forecasted, while Exp6 which is applied on the 29th of February 2004 was
272 designed to find out whether the disappearance of AE1 and AE2 can be forecasted.

273 The prediction results of Exp1 are shown in Fig. 8. In Fig. 8a, we can see that the
274 forecast is almost coincident with the satellite observation and the trajectory of drift
275 buoys, indicating that the generated position of AE1 can be well forecasted by the
276 CSCASS. In addition, the initial migration of AE1 can also be forecasted by the
277 CSCASS (see Fig. 8a and 8f). In order to evaluate the forecasted amplitude of AE1, the
278 amplitude and the distance of eddy centers between the observation and the forecast are
279 also quantified (Table 2: EXP1). From Table 2: EXP1, we can see that the amplitude of
280 forecasting matches well with that of observation, although its amplitude is slightly
281 larger than that of observation. After 4 weeks, the amplitude of the forecast is still close
282 to those of the observation, suggesting that the generation of AE1 can be well predicted
283 by the CSCASS.

284 In order to find out whether the development and movement path of AE1 can be
285 predicted after generation, we continue to carry out Exp2. As shown by the observation
286 (Fig. 9), AE1 moves southwestward along the continental shelf with its amplitude
287 decreasing and again increasing after its generation. This observed southwestward
288 movement is also predicted by the CSCASS (see pink closure curve in Fig. 9a-9d),
289 although a sudden southwestward movement cannot be well predicted (Fig. 9f). In
290 addition, the first attenuation and then enhancement of AE1 can also be predicted by
291 the CSCASS (see Table 2 and Fig. 9b). On the whole, the development and movement

292 path of AE1 can be well predicted by CSCASS for the first four weeks after its
293 generation. After that, the errors between observation and prediction increase
294 significantly, and by the fifth week, the distance between the center of the prediction
295 and the observation become larger, more than 100 km (see Fig. 9e).

296 For further analysis, we carry out Exp3, to look at whether the continued evolution
297 of AE1 and the generation of AE2 can be predicted. This experiment is carried out based
298 on the initial condition of the assimilation on the 31st of December 2003 and the
299 corresponding results are shown in Fig. 10 and Table 2. As shown by the prediction
300 (Fig. 10, Table 2), although with a slightly weak amplitude, the CSCASS can reproduce
301 AE1 after assimilating SLA and SST and predicted its development trend. In addition,
302 the movement path of AE1 cannot be accurately predicted at this period, for instance,
303 the observed AE1 moves directly to southwest (see red solid line and solid circle in Fig.
304 10f), but the predicted movement is firstly toward northeast, then turns to southwest
305 (see blue solid line and solid circle in Fig. 10f). The generation of AE2 cannot be
306 predicted in Exp3, which may be related to the smaller amplitude (<8 cm) of AE2 at
307 this period.

308 The purpose of Exp4 is to look at whether the evolution of AE1 and AE2 can both
309 be reasonably predicted. Since this experiment mainly focuses on the evolution of AE1
310 and AE2, thus Fig. 11 shows only the evolution of AE2 from the second week after
311 generation, that is, from the beginning on the 21st of January 2004 to the fifth week. As
312 shown in Fig. 11, Table 2 and Fig. 14d, the trends of amplitude variation of both eddies
313 can be well predicted with the decreasing of AE1 and slow increasing of AE2. For AE1,

314 the results of the prediction and observation are very close in the first two weeks, with
315 the center of the two almost coincide. The central position of the prediction and
316 observation began to deviate after the third week. For AE2, although the amplitude and
317 movement path are not predicted well at its initial stage, the prediction is slowly
318 approaching to the observation during third to fifth week, and distance between the
319 center of the prediction and the observation is reduced from 132 km at the beginning to
320 81 km at the end (see Fig. 14d the black solid line).

321 As mentioned above, the purpose of Exp5 is to investigate whether the decay of
322 AE1 and the continued development of AE2 can be predicted. From Fig. 12, Table 2
323 and Fig. 14e, we can find that the CSCASS cannot predict the movement path of AE1
324 well in its decay stage: the distance between the center of the prediction and that of the
325 observation is greater than 188 km, and movement direction of the two is not consistent
326 (see red lines and dots in Fig. 12f). But the evolution and moving direction of AE2 can
327 be well predicted at this stage. The amplitude of observation and prediction of AE2 are
328 getting closer with time (Fig. 14e), although the speed of movement of AE2 given by
329 prediction is slower than that of observation (see blue dashed lines and hollow dots in
330 Fig. 12f).

331 The aim of Exp6 is to find whether the disappearance of AE1 and AE2 can be both
332 predicted. As described in Fig. 13, the disappearance of AE1 cannot be well predicted
333 owing to the low amplitude (less than 8 cm) of AE1 at this stage. Similarly, the
334 disappearance of AE2 is also less accurately predicted by the CSCASS (Fig. 14f). The
335 amplitude of AE2 from the observation decays continually at this stage, but the

336 amplitude of the predicted almost keeps constant. In addition, there is large deviation
337 of the direction of movement between prediction and observation for AE2 (see the red
338 solid line and dot in Fig. 13f).

339

340 **4. Conclusions and challenges for forecasting of mesoscale eddy**

341 In this paper, we carry out a series of assimilation and prediction experiments by
342 the CSCASS to assess the production and predictability of mesoscale eddies in the
343 NSCS, along with observations of satellite observed SST, SLA and the trajectory data
344 of drift. The comparisons of AE1 and AE2 observations with CSCASS prediction
345 experiments, which assimilate SLA and SST, show that when the amplitudes of
346 mesoscale eddy are higher than 8 cm, the generation, development, decay and
347 movement of eddies can be well reproduced, but when the amplitude of the mesoscale
348 eddy is lower than 8 cm, the generation and disappearance of mesoscale eddy cannot
349 be well reproduced.

350 The comparisons of AE1 and AE2 through six prediction experiments with
351 observations also show that the generation, evolution and movement path of these two
352 eddies with high amplitude (>8 cm or the ANP greater than 2) can be well predicted by
353 the CSCASS, although the generation mechanism of these two eddies is quite different
354 (Wang et al., 2008). However, when the amplitude of eddies becomes less than 8 cm,
355 the generation position and the movement path cannot be well predicted by the
356 CSCASS.

357 Our results suggested that for powerful mesoscale eddies, a good initial condition

358 after assimilating observations can help to improve their reproduction and predictability.
359 As mentioned above, the mesoscale eddies are related to strong nonlinear processes and
360 are not a deterministic response to atmospheric forcing, thus the quality of mesoscale
361 eddies forecast will depend primarily on the quality of the initial conditions. In addition,
362 the ability of the ocean numerical model to faithfully represent the ocean physics and
363 dynamics is also crucial. Although data assimilation, which combines observations with
364 the numerical model, can provide good initial conditions, it cannot make up for
365 limitations of numerical model algorithms and in its resolution. Hence for high-
366 resolution operational oceanography, numerical models need to be improved using
367 more accurate numerical algorithms and resolution especially in the weakly stratified
368 regions or on the continental shelf.

369 Furthermore, so far most of the information about the ocean variability is obtained
370 remotely from satellites (SSH and SST), the information about the subsurface
371 variability are very rare. Although a substantial source of subsurface data is provided
372 by the vertical profiles (i.e., expendable bathy thermographs, conductivity temperature
373 depth, and Argo floats), the datasets are still not sufficient to determine the state of the
374 ocean. In addition, in order to accurately assimilate the SSH anomalies from satellite
375 altimeter data into the numerical model, it is necessary to know the oceanic mean SSH
376 over the time period of the altimeter observations (Xu et al., 2011; Rio et al., 2014).
377 This is also a big challenge because the earth's geoid is not presented with sufficient
378 spatial resolution when assimilating SSH in an eddy-resolving model. With the advent
379 of the SWOT (Surface Water and Ocean Topography) satellite mission in 2020, it

380 should be possible to better resolve and forecast the mesoscale features in eddy
381 resolving ocean forecasting systems.

382

606 Fig. 14 The amplitude of AE1 and AE2 derived from observation SLA and the six forecast SLA,
 607 and distance of eddy centers between the observation, assimilation and forecast SLA's, respectively.
 608 The red and green histograms indicated the AE1 amplitudes from observation and prediction
 609 respectively. The pink and blue histograms expressed the AE2 amplitudes from observation and
 610 prediction respectively. The cyan star solid (dash) line shows the distance of the center between
 611 observation and prediction (assimilation) AE1. The black diamond solid (dash) line shows the
 612 distance of the center between observation and prediction (assimilation) AE2.
