6 **Abstract.** Due to its toxic nature and its high potential for biomagnification, mercury is a pollutant of concern. Understanding
7 the marine biogeochemical cycle of mercury is crucial as consumption of mercury enriched marine fish is the most important
8 pathway of human exposure to monomethylmercury, a neurotoxin. However, due to the lack of long-term marine records, the
9 role of the oceans in the global mercury cycle is poorly understood. We do not have well-documented data of natural mercury
10 accumulations during changing environmental conditions, e.g. sea surface conditions in the ocean. To understand the influence
11 of different sea surface conditions (climate-induced changes in ice coverage and biological production) on natural mercury
12 accumulation, we used a continuous ~ 170 m Holocene biogenic sedimentary record from Adélie Basin, East Antarctica, which
13 mainly consists of silica-based skeletons of diatoms. We performed Principal Component Analysis and regression analysis on
14 element concentrations and corresponding residuals, respectively to investigate the link between sediment mercury
15 accumulation, terrestrial inputs, and phytoplankton productivity. Preindustrial mercury in the remote marine basin shows
16 extremely high accumulation rates (median: 556 $\mu\text{g m}^{-2} \text{yr}^{-1}$) that displayed periodic-like variations. Our analyses show that
17 the variations in total mercury concentrations and accumulation rates are associated with biological production and related
18 scavenging of water phase mercury by rapidly sinking algae or algae-derived organic matter after intense algae blooms. High
19 accumulation rates of other major and trace elements further reveal that in regions of high primary productivity, settling of
20 biogenic materials removes a large fraction of dissolved or particulate bound elements from free water phase through
21 scavenging or biological uptake. The link between mercury cycling and primary production will need to be considered in future
22 studies of the marine mercury cycle under primary production enhancement through climatic, temperature, and nutrient
23 availability changes.

24 **1 Introduction**

25 Mercury (Hg) is a metal of environmental concern due to its ability to be transported through the atmosphere from industrial
26 point sources to remote regions and its transformations into highly bioaccumulative and neurotoxic methylated forms. In the

27 global biogeochemical cycle of Hg, the ocean, as the dominant physical feature of our planet Earth, is of specific concern. A
28 substantial amount of Hg (~ 80 %) which is emitted to the atmosphere from natural and anthropogenic sources reaches the
29 ocean (Horowitz et al., 2017; Schartup et al., 2019) and ocean sediments are considered to be the ultimate sink of Hg on a
30 timescale of tens of thousands of years (Fitzgerald et al., 2007; Selin, 2009; Amos et al., 2013). Despite the important role of
31 marine sedimentation in the global Hg biogeochemical cycle, little is known about the rates or amount of Hg accumulation in
32 marine sediments, especially in the open ocean. In contrast to the well-studied Hg cycling in terrestrial environments,
33 knowledge about the temporal and spatial distribution of Hg in the marine environment is limited to model estimations (Mason
34 and Sheu, 2002; Sunderland and Mason, 2007), water column measurements (Cossa et al., 2011; Lamborg et al., 2014; Canário
35 et al., 2017), and very few sediment measurements (Kita et al., 2013; Aksentov and Sattarova, 2020). A main reason for our
36 limited understanding of the fate of Hg in the oceans is the lack of high resolution marine sedimentary records, especially from
37 the deep ocean (Zaferani et al., 2018).

38 Hg input to the ocean is primarily through atmospheric deposition (Mason et al., 1994; Driscoll et al., 2013). After deposition,
39 as either mercuric ion (Hg^{2+}) or elemental Hg (Hg^0), Hg can be reduced to Hg^0 and evaded to the atmosphere, or scavenged
40 from the water column by particulate matter and eventually buried in deep-sea sediments (Mason et al., 2012; Lamborg et al.,
41 2014). Most marine surface waters are believed to be close to equilibrium between Hg deposition and evasion or saturated in
42 Hg^0 due to biologically mediated (Mason et al., 1995; Rolfhus and Fitzgerald, 2004; Whalin et al., 2007) and photochemical
43 reduction (Amyot et al., 1997; Mason et al., 2001) followed by re-emission of Hg^0 to the atmosphere. It has been estimated
44 that almost 96 % of the deposited Hg to the ocean is lost through evasion from the surface, and only 30 % of the Hg flux that
45 reaches the deep ocean is preserved in sediments (Mason and Sheu, 2002). However, other studies indicate that the ocean
46 surface waters become a sink for atmospheric Hg at the high nutrient levels and related high primary productivity (Soerensen
47 et al., 2016).

48 There are contradictory statements about the Hg deposition and evasion to/from different surface waters. Early works suggest
49 that Hg evasion is high in productive upwelling regions of the ocean due to enhanced biological reduction (Fitzgerald et al.,
50 1984; Mason and Fitzgerald, 1993). More recent studies, with higher spatial and temporal resolutions, suggest lower Hg
51 evasion in productive regions (O'Driscoll et al., 2006; Qureshi et al., 2010; Soerensen et al., 2013; Soerensen et al., 2014).
52 Measurements of Hg from these recent studies show relatively low concentrations of atmospheric and surface water phase Hg^0
53 in regions with high productivity compared to areas with lower productivity. These studies related their observation to sorption
54 and scavenging of Hg by suspended organic particles. They suggested that removal of Hg^{2+} associated with sorption and
55 scavenging by suspended organic particles in productive regions reduces the amount of available Hg^{2+} for reduction and re-
56 emission. Therefore applying the model estimates across the entire ocean introduces substantial uncertainty and one area in

57 particular that highlights this uncertainty is the underestimation of the role of biological productivity as a major vector of Hg
58 sedimentation in the oceans.

59 The marine biogeochemical cycle, especially sedimentation of many elements (Fowler and Knauer, 1986; Morel and Price,
60 2003; Schlesinger and Bernhardt, 2013), including Hg (Kita et al. 2013; Lamborg et al., 2016; Zaferani et al., 2018), in the
61 ocean is controlled directly and indirectly by biological productivity. Biogenic particles control the distribution of elements
62 through primary production, sinking, and decomposition (Fowler and Knauer, 1986). Besides direct uptake across cell
63 membranes through active metabolism, phytoplankton and sinking biogenic particles can scavenge and remove many other
64 elements from the dissolved phase and transport them to the deep sea. Sinking speed of biogenic particles plays an important
65 role in the final fate of those elements. Rapidly sinking particles such as diatom agglomerates transfer elements to the deep sea
66 (Fowler and Knauer, 1986; Smetacek et al., 2012), whereas elements associated with the slowly sinking particulates will
67 release back to the water phase through remineralization (Fowler and Knauer, 1986). In areas where pronounced seasonal
68 blooms take place, phytoplankton species appear to reach the deep-sea floor relatively fast and intact. Seasonal blooms in the
69 surface waters will also cause temporally variable fluxes of elements in the deep ocean (Fowler and Knauer, 1986; Michel et
70 al., 2002; Pilskaln et al., 2004). For Hg, these findings are supported by water column (Lamborg et al., 2014) and marine
71 sediment measurements (Kita et al., 2013; Aksentov and Sattarova, 2020). Lamborg et al. (2014) described a nutrient-like
72 distribution of Hg in the water column of oceans. This study indicates that similar to carbon (C) and phosphorus (P), Hg shows
73 higher concentrations in the deep water due to its release during organic matter decomposition. Kita et al. (2013) found a
74 positive correlation between Hg and the absolute abundance of phytoplankton species in sediments of the Caribbean Sea. Hg
75 in these sediments was assumed to be a result of Hg binding by phytoplankton depositing Hg-bearing organic matter in the
76 photic zone. A similar conclusion was reached by Aksentov and Sattarova (2020) who used a thermo-scanning technique to
77 detect Hg forms. They found that biological productivity controlled the Hg burial in Northwest Pacific bottom sediments and
78 that the forms of Hg depended on the diatom content.

79 These observations can be due to Hg—phytoplankton interactions and up-take or binding of Hg from the water by
80 phytoplankton (Le Faucheur et al., 2014; Mason et al., 1996). This interaction controls the flux of Hg from the water column
81 to sediments and facilitates the downward flux of Hg to the seafloor (Soerensen et al., 2014; Soerensen et al., 2016; Lamborg
82 et al., 2016; Zaferani et al., 2018), which, as mentioned, has traditionally been considered to be slow in its nature. Thus,
83 underestimating the role of biological productivity in the marine biogeochemical cycle of Hg may lead to an overestimation
84 of re-emission fluxes from surface water and an underestimation of the Hg flux to deep-sea sediments.

85 In this context, the Southern Ocean is of particular interest due to its high concentrations of nutrients and related elevated
86 primary productivity (Arrigo et al., 1998). In the Southern Ocean, diatoms are major primary producers (Crosta et al., 2005).

87 Their siliceous cell walls preserve well in sediments and form diatom ooze (Fütterer, 2006). The sedimentation rate of diatom
88 ooze is high, estimated to reach up to 2 cm yr^{-1} (Escutia et al., 2011), making diatom ooze deposits around Antarctica a unique
89 geochemical archive to study the influence of primary productivity as well as natural and anthropogenic changes on the marine
90 biogeochemical cycle of Hg.

91 Despite providing a unique geochemical archive, studies on Hg cycling in the Southern Ocean, particularly in the Antarctic
92 region, are generally limited to water column (Cossa et al., 2011; Nerentorp Mastromonaco et al., 2017b; Canário et al., 2017),
93 surface water/air (Nerentorp Mastromonaco et al., 2017a; Wang et al., 2017), and ice core analyses (Vandal et al., 1993). Cossa
94 et al. (2011) showed a nutrient-like distribution of Hg in water column that ranged between 0.6 and 2.8 pmol L^{-1} . Nerentorp
95 Mastromonaco et al. (2017b) found higher total Hg concentration than Cossa et al. (2011) with no significant vertical
96 variations. Both studies reported seasonal variations in Hg concentrations and related them to seasonal variations of
97 atmospheric Hg deposition (Cossa et al., 2011; Nerentorp Mastromonaco et al., 2017b) as well as the Hg inputs from melting
98 sea ice and snow (Nerentorp Mastromonaco et al., 2017b). Total Hg concentrations in the Atlantic sector of the Southern Ocean
99 obtained during a study by Canário et al. (2017) were also, in general, comparable to those obtained by Cossa et al. (2011)
100 except for some stations that showed higher total Hg concentrations. Canário et al. (2017) attributed these differences to the
101 different stages of phytoplankton bloom during the sampling. This led to lower dissolved Hg in water in the middle-end stage
102 of the bloom compare to the beginning stage of the bloom, owing to the Hg uptake by phytoplankton (Canário et al. 2017).
103 Measurements of gaseous elemental mercury (GEM) and dissolved gaseous mercury (DGM) in surface water showed spatial
104 and seasonal variations as well (Nerentorp Mastromonaco et al., 2017a; Wang et al., 2017). These studies related the increase
105 of DGM and GEM concentrations to the presence and absence of sea ice. Sea ice that could prevent Hg evasion to the
106 atmosphere, could initially lead to an increase in Hg emissions to the atmosphere when diminishing. Hg concentrations in an
107 ice core covering the past 34 Kyr, varied between 0.0005 and $0.0021 \text{ } \mu\text{g kg}^{-1}$, corresponding to depositional fluxes of 0.009
108 and $0.031 \text{ } \mu\text{g m}^{-2} \text{ yr}^{-1}$ during the Holocene and the Last Glacial Maximum, respectively (Vandal et al., 1993). Vandal et al.
109 (1993) attributed the observed enhanced Hg flux during colder periods to marine biological productivity and emissions of
110 volatile Hg compounds from the ocean. Given the different results of the existing studies point to the gaps in our understanding
111 of Hg behavior in productive remote areas which warrants further investigation in the Southern Ocean.

112 In a previous paper, we discussed the accumulation of anthropogenic Hg in sediments of Adélie Basin, offshore East
113 Antarctica. The ~ 2 -fold increase in Hg concentrations and accumulation rates in the upper $\sim 2.80 \text{ m}$ depth of the core was
114 attributed to the onset of the industrial revolution and the strong increase in coal burning at $\sim 1850 \text{ CE}$ (Zaferani et al., 2018).
115 Here, we discuss the natural processes (e.g. changes in biogenic and terrestrial material fluxes) that controlled Hg accumulation
116 in the same sediment core prior to 1850 CE throughout the past 8600 years. We investigated a continuous $\sim 170 \text{ m}$ long
117 Holocene laminated diatom ooze sediment record from the Adélie Basin. Covering almost the entire Holocene, the core allows

118 the determination of natural variations of Hg accumulation rates in these sediments prior to major anthropogenic influences.
119 Our main objective was to investigate the influence of different Hg sources, climate-induced changes in biological productivity
120 and terrestrial fluxes (through melting of glacier ice), which have controlled the sequestration of Hg in these sediments. To
121 evaluate the influence of different biogeochemical processes on the Hg accumulation in sediments, with an emphasis on the
122 role of changes in planktonic productivity, we combined the data on Hg accumulation with data derived from multi-element
123 analyses.

124

125 **2. Materials and methods**

126 **2.1 Study site and core collection**

127 Sediments of the Adélie Basin were collected during the Integrated Ocean Drilling Program (IODP) Expedition from hole
128 U1357B 318 in 2010. U1357B is located on the continental shelf off Wilkes Land at the Mertz Glacier polynya (region of
129 open water surrounded by sea ice), Antarctica (66°24.7990' S, 140°25.5705' E) at about 1021.5 m water depth (Escutia et al.,
130 2011) (Fig 1). The total length of the recovered core is 170.7 m, corresponding to nearly the entire Holocene (Escutia et al.,
131 2011). The core was sliced by 5cc plastic scoops to 1 cm slices. Samples in the upper core (3.2–25.05 mbsf) were taken at ~
132 40 cm intervals (a resolution of ~ 20 years) and ~ 400 cm intervals (a resolution of ~ 200 years) in deeper sections (25.05–
133 170.35 mbsf), resulting in a total of 78 samples. Age data and age model (which is based on Compound-specific ¹⁴C dating)
134 were obtained from Yamane et al. (2014).

135 The sediment core is characterized by light and dark laminations which are undisturbed by sea-level changes or glacial erosion
136 (Denis et al., 2006; Escutia et al., 2011). Light laminations correspond to spring seasons when light and high nutrient levels
137 promote intense phytoplankton blooms and are mainly composed of biogenic materials (mostly diatom with minor abundance
138 of silicoflagellates, sponge spicules, radiolarians, and foraminifers). Dark layers correspond to the summer/autumn season
139 when sea ice has retreated, and nutrient levels are low. Dark laminations are composed of a mixture of biogenic and terrigenous
140 materials resulting from summer production in open water, with glacial and subglacial inputs, respectively. High levels of
141 primary production in surface water of this region, coupled with rapid fluxes of biogenic debris directly to the seafloor, led to
142 high sedimentation rates of up to 2.0 cm yr⁻¹ during the past 10,000 years (Escutia et al., 2011).

143 **2.2 Analyses of mercury and major and trace metals**

144 All samples were freeze-dried and ground using a glass pestle prior to geochemical analysis. Total Hg was determined by
145 thermal decomposition followed by pre-concentration of Hg on a gold trap and CVAAS Hg detection using a Milestone DMA-

146 80 analyzer (US EPA Method 1998). The quality of the analysis was ensured by including a certified reference material (CRM)
147 (Canmet LKSD-4 = $190 \pm 17 \text{ ng g}^{-1}$) alongside the analyzed samples. The average measured concentration for LKSD-4 was
148 $197 \pm 11 \text{ ng g}^{-1}$. Replicate analyses ($n = 20$) were always within an RSD of 10 % of the certified value.

149 The samples were analyzed for concentrations of silicon (Si), titanium (Ti), zirconium (Zr), sulfur (S), calcium (Ca), potassium
150 (K), aluminum (Al), yttrium (Y), manganese (Mn), strontium (Sr), iron (Fe), lead (Pb), copper (Cu), zinc (Zn), arsenic (As),
151 bromine (Br), nickel (Ni), chlorine (Cl), and rubidium (Rb) by energy dispersive X-ray fluorescence (ED-XRF). The
152 calibration method, accuracy, and precision are described in detail in Cheburkin and Shotyk (1996). The CRMs (Canmet
153 LKSD-4, NRC/CNRC-PACS-2, NRC/CNR-Mess-3, and NCS-DC75304) and replicates were measured in each set of samples
154 for accuracy and precision control. Repeated analysis of CRMs gave relative standard deviation (SRD) less than 10 % for Si,
155 Al, Ca, Y, Sr, Zr, Br, and Rb, 6–15 % for Ti, K, Zn, S, Fe, Mn, and Pb, 6–19 % for Cl, 10–20 % for Ni, 9–14 % for Cu, and
156 14–22 % for As.

157 **2.3 Statistical analyses**

158 Principal component analysis (PCA) was applied to the major and trace element concentrations to identify processes
159 controlling the variability of elements in the sediments. When there is a complex set of variables, PCA is used to reduce a large
160 number of variables to a new set of artificial variables, called principal components. Each component includes variables with
161 a similar down core pattern. The principal components are then interpreted in terms of relevant geochemical processes that can
162 control the variability of the major and trace elements in the sediments. The derived interpretation from PCA was then
163 combined with the Hg data to examine the processes that could affect Hg accumulations. The analysis was performed on the
164 standardized concentration data using Z-scores (expressed in terms of standard deviations from their means). Regressions
165 analysis of the corresponding residuals was used to establish relationships between the abundance of elements, by considering
166 Si concentration as an independent variable and other element concentrations as dependent variables. Correlation analysis and
167 PCA were performed using the statistical software SPSS 25.0.

168 **3. Results and discussion**

169 **3.1 Geochemical processes controlling the distribution of the elements in the sediments**

170 Concentration profiles and accumulation rates of Si, Al, K, Ti, S, Ca, Zn, Fe, Br, As, and Cl are shown in Fig. 2-5. The
171 preindustrial geochemical record of Adélie Basin sediments is generally characterized by periodic-like variations in the relative
172 abundance of major and trace elements. The records of element accumulation rates largely follow those of periodic-like
173 variations of concentrations and show no significant trend with depth (except Cl).

174 Si has the highest concentration of all elements in the sediments. On one hand, Si is associated with the flux of terrestrial
175 derived mineral components and on the other hand with siliceous phytoplankton, protozoans, protists, plant phytoliths, and
176 sponge spicules (Croudace and Rothwell, 2015). Si is mainly biogenic in origin in Adélie Basin sediments, dominated by
177 diatoms (Escutia et al., 2011), and contribution of terrigenous Si is low. Therefore, it is used as a proxy for diatom abundance.
178 The record of Si concentrations shows periodic-like variations by a factor of ~ 2 between 21 % and 50 %, with a median of 33
179 %, corresponding to 70 % SiO_2 or biogenic silica. Concentrations of Al, K, and Ti (as indicators of changes in the flux of
180 lithogenic materials) range between ~ 1.6 – 7.3 %, ~ 0.37 – 1.11 %, and ~ 716 – 1778 mg kg^{-1} , respectively. S and Ca
181 concentrations, which are associated with the biogenic productivity, vary between ~ 0.13 – 0.87 % and 0.72 – 1.49 %,
182 respectively. Ca concentration indicates that calcite producing microorganisms are of minor importance in the Adélie Basin.
183 Concentration of Zn, an important micronutrient for marine phytoplankton (Morel et al., 1994), ranges between ~ 96 and 216
184 mg kg^{-1} . Fe is another essential micronutrient for marine primary production (Smetacek et al., 2012) and biochemical processes
185 of phytoplankton such as photosynthesis, respiration, and nitrogen fixation (Lohan and Tagliabue, 2018). Concentration of Fe
186 varies between ~ 1.05 and 3.46 %, which is similar to other siliceous sediments but lower than the reported concentration in
187 other ocean sediments (Chen et al., 1996). Fe concentrations increase at 66.45 m depth to the top of the core by a factor of \sim
188 1.6 (from a median of ~ 1.50 % below the 66.45 m depth to ~ 2.40 % above the 66.45 m depth). This is attributed to the upward
189 transport of Fe under anoxic conditions. Chlorine was found to be another major component in these sediments. Cl can go
190 through biological pathways (incorporation into algae) and reach the sediments by the fast-sinking detritus (Leri et al., 2015).
191 Concentrations vary between ~ 1.3 and 19 %, with a median of median 4.5 %, and show a decrease from the top to the bottom
192 of the core which is likely attributed to the increasing mineralization of organic matter with age and the release of chloride
193 through reductive dechlorination.

194 The PCA resulted in five components, explaining almost 82 % of the total variance (Table 1). The first component (Cp1),
195 explains 33 % of the variance and shows large (> 0.7) positive loadings of Mn, Ti, Rb, Zr, K, and Y and moderate positive
196 loading of Fe. The second component (Cp2), which explains 20 % of the variance, is characterized by large positive loadings
197 of Al, Si, S, and Cl and moderate positive loading of K and Ca. The third component (Cp3) explains 17 % of the variance and
198 shows large positive loadings of Zn, Cu, and Ni and moderate positive loading of Fe. The fourth and fifth components (Cp4
199 and Cp5) account for 7 and 5 % of the variance, respectively. Cp4 is characterized by high positive loadings for Hg and As
200 and moderate negative loading of Pb. Cp5 shows positive loadings for Sr and Ca.

201 In general, results of PCA imply that opening and closing of the polynya and biological production are the most important
202 factors influencing sedimentation in the Adélie Basin. This has been shown by loadings of elemental proxies for terrigenous
203 and biological material inputs. Briefly, Cp1, which includes positive loadings of lithogenic elements, represents the variability
204 of terrigenous inputs. Melting of ice releases trapped lithogenic material into the water and leads to the sinking of lithogenic

205 particles and their sedimentation. Cp2 comprises loadings of elements of both biogenic and terrigenous sources. This
206 component appears to reflect phytoplankton blooms and export of biological materials. After ice melt, when the ice is opening,
207 favorable conditions for biological productivity lead to phytoplankton blooms and export of biogenic materials to the seafloor
208 (Denis et al., 2006). Biogenic material is mainly opal because diatoms are a major component of blooms in the Adélie Basin
209 (Escutia et al., 2011). The sinking of diatoms from the surface and their sedimentation can cause scavenging of elements during
210 bloom time. Al shows positive loadings in this component rather than in Cp1. This, other than association with the flux of
211 aluminosilicates material can also be attributed to the scavenging of Al by diatom particles (Moran and Moore, 1992). Cl also
212 shows loading in Cp2. The possible explanation for the observed covariation is that marine phytoplankton is rich in
213 polyunsaturated lipids and can account as chlorination substrates (Leri et al., 2015). However, the organic C content of Adélie
214 Basin sediments is generally low (between 1 and 2 wt %), and we hypothesis that some of the Cl must be in an inorganic form
215 trapped in sediments owing to high sedimentation rates. Cp3 is mainly characterized by elements that are associated with the
216 organic fraction of diatom cells. This component appears to reflect the remineralization process like decomposition of organic
217 particles during sinking. Trace elements associated with organic parts of cells can be released back into the water column
218 during decomposition. Therefore, cellular locations of elements, i.e. opal frustules of diatoms or organic matter of diatom cells,
219 created different components of Cp2 and Cp3. Cp4 consists of organic particle reactive metals, e.g. Hg and Pb. The possible
220 explanation for not having these two particle reactive metals in Cp2 is that some of these two metals begin to enter the system
221 after ice melting, while Cp2 shows scavenging of elements by diatoms that are already present in the water column. Since Pb
222 and Hg are negatively correlated, this component cannot reflect a pollution signal. The reason for that could be the
223 characteristic of Pb that decreases its impact in remote areas such as Antarctica. Atmospheric Pb is associated with particles
224 and therefore is rapidly removed by wet and dry deposition. Moreover, Southern Ocean circumpolar vortex that isolates
225 Antarctica from the other continental landmasses in the Southern Hemisphere will further limit Pb transport to Antarctica.
226 Covariation of Ca and Sr in Cp5 represents sedimentation of planktonic foraminifera, which appears to be of minor importance
227 here.

228 Cp1 explains 33 % of the variance and accounts for much of the variability/process which controlled the geochemical
229 composition of these sediments. However, the high concentration of Si and low concentrations of terrigenous elements imply
230 that in an environment like Adélie Basin, with extremely high productivity, input of lithogenic materials is changing while
231 different diatom taxa are always present in the system, e.g. as sea ice-associated and open ocean diatom (Escutia et al., 2011).

232 It has been shown before that seasonal blooms in ocean surface waters result in temporary variable fluxes of elements to the
233 deep ocean (Fowler and Knauer, 1986; Michel et al., 2002; Pilskaln et al., 2004). Although the core was not sampled at a one-
234 year resolution in our study, we suggest that the fluctuations of elemental concentrations are likely related to the seasonal
235 blooms and variation of sea surface conditions like ice melting and freezing and its subsequent biological or terrestrial materials

236 exports. Sampling in light (associated with spring) or dark (associated with summer/autumn) laminae, which contains different
237 amounts of biogenic or terrestrial materials can cause the observed variations (see Sect. 2.1).

238 The element concentrations are comparable to other published sediment data, while the accumulation rates are much higher
239 than other reported values. The existence of rapidly settling particles in the Adélie Basin can explain the high element
240 accumulation rates. When nonessential elements and essential elements show high accumulation rates, it is tempting to suggest
241 that most elements in the water column of Adélie Basin are subjected to removal by intense phytoplankton blooms through
242 consumption or scavenging. This agrees with the study of Fowler and Knauer (1986) that demonstrated the role of large
243 particles in the transport of elements through the oceanic water column. Aggregation of diatoms, which creates large particles
244 (Turner, 2015), sink to the seafloor and can create a space in which elements can be trapped (Shanks and Trent, 1979). This
245 enhances removal of elements from the water column and their sedimentation as well.

246 **3.2 Holocene record of mercury concentrations and accumulation rates**

247 In the preindustrial period, i.e. from the bottom of the core at ~ 170 m to 2.80 m depth (8600 years ago to ~ 1850 CE), the Hg
248 record shows no obvious trend with depth but rather periodic-like variations. Hg concentrations fluctuate by a factor of about
249 2 between 12.6 and 21.1 $\mu\text{g kg}^{-1}$ within 170–137 m depth and between 21.7 and 44.6 $\mu\text{g kg}^{-1}$ within 137–2.80 m depth of the
250 core, with two more pronounced peaks at around 9.99 and 8.20 m depth (Fig. 2 and 3). The lower concentration of Hg within
251 170–137 m depth of the core is probably attributed to cooler conditions in Adélie Basin (Crosta et al., 2007) and sea ice cover
252 during this period. Hg accumulation rates in the preindustrial period (Fig. 4 and 5) largely follow the Hg concentration record,
253 with periodic-like variations and a median of 556 $\mu\text{g m}^{-2} \text{yr}^{-1}$, which largely surpass the reported Hg deposition rates to the
254 oceans (Mason and Sheu, 2002).

255 The high preindustrial Hg accumulation rates in Adélie Basin sediments cannot be explained by preindustrial atmospheric Hg
256 depositions alone, which did not exceed 20 $\mu\text{g m}^{-2}$ as recorded in an Antarctic ice core (Vandal et al., 1993). Therefore, non-
257 atmospheric sources, such as dissolved water phase Hg or terrestrial inputs, are needed for the observed high Hg enrichment
258 in these sediments.

259 To identify driving forces behind the variations in Hg accumulation we used our PCA results. PCA demonstrated that two
260 main processes, i.e. biogenic productivity and lithogenic inputs, controlled the flux of elements to Adélie Basin sediments.
261 The component scores, which illustrate the depth dependency of the extracted components, are characterized by see-saw
262 patterns throughout the entire core. This indicates different contributions of biogenic and terrigenous inputs most likely
263 associated with spring and summer/autumn seasons, respectively.

264 The variance of Hg was not captured by Cp1, Cp2, or Cp3. Hg instead forms a group on Cp4 together with positive loading of
265 As and negative loading of Pb. The absence of significant loading of Hg on Cp1, Cp2, and Cp3 (Table 1) and the lack of
266 similarity between component scores and Hg concentrations (Fig. 6 and 7), in the preindustrial period, indicates that Hg fluxes
267 are not significantly influenced by changes in lithogenic inputs through ice melting. These results further indicate that changes
268 in the contribution of biogenic material can not explain the variation in Hg accumulation in the sediments.

269 Although the high Hg accumulation rates observed in the Adélie Basin sediments could not be explained by atmospheric Hg
270 deposition, but we expect that the Hg flux from the atmosphere will probably increase during algae blooms attributed to the
271 removal of dissolved Hg through scavenging by algae. Hg removal from the upper water column by diatom organic matter
272 will also likely decrease Hg re-evasion to the atmosphere as previously assumed in model studies (Soerensen et al., 2014;
273 Soerensen et al., 2016).

274 We have hypothesized that the high Hg enrichment in Adélie Basin sediments has been caused by scavenging of dissolved
275 water phase Hg by a large amount of fast sinking algal debris. To proof this hypothesis we calculated the maximum amount
276 of Hg which could be scavenged by a single bloom event using the Hg concentration of $271 \pm 78 \text{ pg L}^{-1}$ in Antarctic Bottom
277 Water, as determined by Cossa et al. (2011). The amount of Hg in a water column of one m^2 and 1000 m depth would then
278 amount to $271 \pm 78 \text{ } \mu\text{g}$. This means that only about 2-3 algae blooms and scavenging events per year are necessary to obtain
279 the average Hg accumulation rate in Adélie Basin diatom ooze sediments, i.e. $556 \pm 137 \text{ } \mu\text{g m}^{-2} \text{ yr}^{-1}$. This appears to be likely
280 taking into account that bloom events are frequent during Antarctic summer and that the sinking speed of diatom agglomerates
281 at Adélie Basin is high (100-400 m per day) (Jansen et al., 2018). The annual cycle of water mass transformation beneath the
282 Mertz Glacier polynya system (Williams et al., 2008) and the exchange of water masses can rapidly “refill” the Hg inventory
283 in the water column after a scavenging event. While algal bloom is a local event at the surface water of the Adélie Basin, the
284 exchange of water masses, which have not been affected by algae blooms, could refill the Hg inventory in the water column
285 (Fig. 8).

286 The main reason for not finding any statistical relation between Hg and biogenic materials is that the amount of algal material
287 during blooms is always large and therefore not a limiting factor for the scavenging of Hg. There has always been excess algal
288 material within or passing through the water column to scavenge all water column Hg. Thus, we assume that nearly all Hg in
289 the water column is removed through scavenging during diatom blooms, but that Hg scavenging events occur less frequently
290 during winter and summer/autumn seasons when primary productivity is lower and open ice expansion is at its maximum.
291 Similar to other elements, the periodic-like variations observed in the preindustrial Hg record. The influence of periodically
292 climatic changes of phytoplankton activity on periodical changes of Hg content was suggested before for the Caribbean Sea
293 (Kita et al., 2013). It is likely, that the periodic-like variations observed in the Adélie Basin Hg record are also attributed to the

294 seasonal export of biological materials. There is also evidence, based on Hg levels in water (Canário et al. 2017) that relevant
295 to different development stages of a phytoplankton bloom, different amounts of dissolved Hg can be taken up by
296 phytoplankton. However, investigation at seasonal resolution is needed to further confirm our observations and hypotheses.

297 **4. Conclusions**

298 Investigation of Antarctic biogenic bottom sediments revealed that biological productivity and related scavenging of water
299 phase Hg by rapidly sinking algae or algae-derived organic matter controlled preindustrial Hg accumulation in Adélie Basin,
300 Antarctica. Our study suggests that the periodic-like variations in total Hg concentrations and accumulation rates are likely
301 associated with the opening and closing of polynya and its related changes in biological productivity. Although the high Hg
302 accumulation in diatom ooze does not represent the Hg sedimentation process across all the world's oceans, our data shows
303 that Hg scavenging by algae or fast sinking algae-derived organic matter is a key process controlling the sequestration of Hg
304 in marine sediments; and therefore the marine biogeochemical cycle of Hg in general. This can be similar to the association
305 between very high benthic organic C fluxes with diatom production at the surface water which can be accelerated by
306 aggregation (Sachs et al., 2009).

307 Our observations also suggest that re-emission of Hg from ocean surface waters as a result of reduction of Hg (II) might be
308 reduced due to Hg scavenging by algae, at least in areas of high primary productivity ecosystems comparable to Adélie Basin
309 ecosystem setup. Moreover, Hg fluxes to marine sediments might be higher than previously assumed in global model
310 estimations. More data from marine sediments is needed to support this assumption. A future increase in marine productivity
311 including algae blooms especially in coastal areas and semi-closed shallow seas will likely increase the Hg flux to bottom
312 sediments. The model study of Soerensen et al. (2016) for the Baltic Sea might serve as an example for changes in marine Hg
313 cycling caused by eutrophication. The area of the seafloor which is covered by remains of calcareous phytoplankton needs to
314 be considered in future studies as well owing to the role of calcareous species on Hg content (Kita et al., 2013).

315

316 *Author contributions.* S. Zaferani carried out the analyses. H. Biester planned the study and supervised the findings of this
317 work. The manuscript is written by both authors.

318 *Competing interests.* The authors declare that they have no conflict of interest

319 *Acknowledgments.* This research was supported by TU Braunschweig. We thank P. Schmidt and A. Caelean for technical
320 assistance, Dr. DS. McLagan for the constructive comments on the manuscript.

476

477 Figure 2: Down core records of Si, Al, K, Ti, S, Fe, Zn, Cl, Ca, Br, As, and Hg concentrations of Adélie Basin sediments.

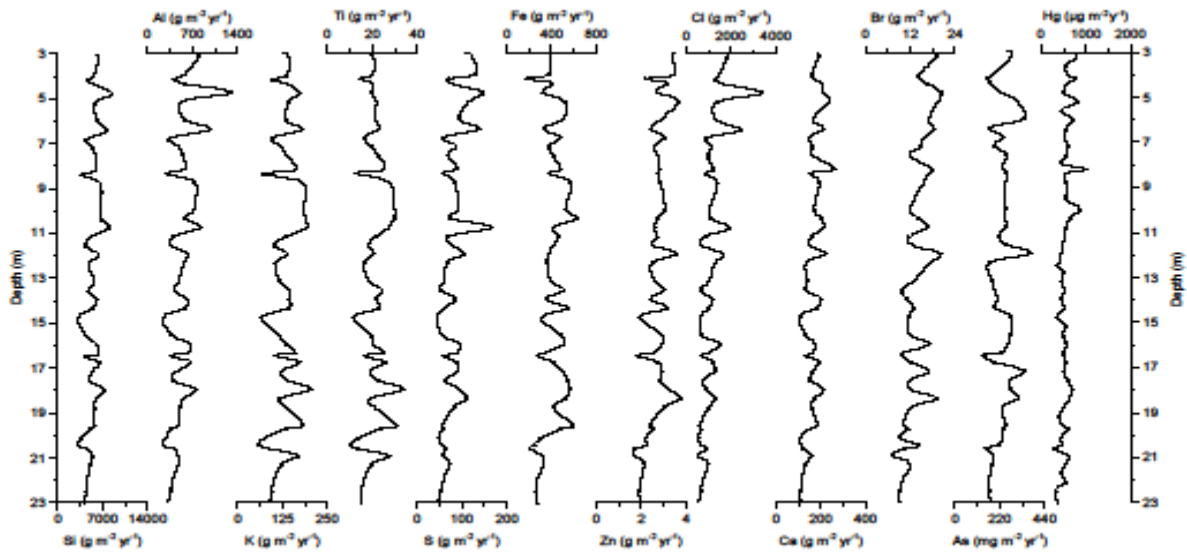

478

479 Figure 3: Down core records of Si, Al, K, Ti, S, Fe, Zn, Cl, Ca, Br, As, and Hg concentrations of Adélie Basin sediments for
 480 the top 23 m of the core.

481

482 Figure 4: Down core records of Si, Al, K, Ti, S, Fe, Zn, Cl, Ca, Br, As, and Hg accumulation rates of Adélie Basin sediments.

483

484 Figure 5: Down core records of Si, Al, K, Ti, S, Fe, Zn, Cl, Ca, Br, As, and Hg accumulation rates of Adélie Basin sediments
 485 for the top 23 m of the core.

486

487 Figure 6: Depth records of scores of the principal components extracted by PCA on the elemental composition of the sediments
 488 along with Z-score of Hg of the Adélie Basin sediments.

489

490 Figure 7: Depth records of scores of the principal components extracted by PCA on the elemental composition of the sediments
 491 along with Z-score of Hg of the Adélie Basin sediments for the top 23 m of the core.

492

493 Figure 8: Adélie Basin schematic Hg cycle model indicating the processes controlling Hg deposition and accumulation under
 494 high primary production. Fast-sinking diatom particles remove dissolved water phase Hg from the water column through
 495 scavenging (Figure is adapted from Jansen et al., 2018).
