42 **ABSTRACT**

43 After more than a decade of shallow convection, deep convection returned to the Irminger Sea in  
44 2008 and occurred several times since then to reach exceptional convection depths (>1,500 m) in  
45 2015 and 2016. Additionally, deep mixed layers larger than 1600 m were also reported Southeast of  
46 Cape Farewell in 2015. In this context, we used Argo data to show that deep convection occurred  
47 Southeast of Cape Farewell (SECF) in 2016 and persisted during two additional years in 2017 and  
48 2018 with maximum convection depth larger than 1,300 m. In this article, we investigate the  
49 respective roles of air-sea buoyancy flux and preconditioning of the water column (ocean interior  
50 buoyancy content) to explain this exceptional 4-year persistence of deep convection SECF. We  
51 analyzed the respective contributions of the heat and freshwater components. Contrary to the very  
52 negative air-sea buoyancy flux that was observed during winter 2015, the buoyancy fluxes over the  
53 SECF region during winters 2016, 2017 and 2018 were close to the climatological average. We  
54 estimated the preconditioning of the water column as the buoyancy that needs to be removed (B)  
55 from the end of summer water column to homogenize it down to a given depth. B was lower for  
56 winters 2016 – 2018 than for the 2008 – 2015 winter mean, due especially to a vanishing  
57 stratification from 600 m down to ~1,300 m. It means that less air-sea buoyancy loss was necessary  
58 to reach a given convection depth than in the mean and once convection reached 600 m little  
59 additional buoyancy loss was needed to homogenize the water column down to 1,300 m. We  
60 showed that the decrease in B was due to the combined effects of the local cooling of the  
61 intermediate water (200 – 800 m) and the advection of a negative S anomaly in the 1,200 – 1,400 m  
62 layer. This favorable preconditioning permitted the very deep convection observed in 2016 – 2018  
63 despite the atmospheric forcing was close to the climatological average.

71 **1. INTRODUCTION**

72 Deep convection is the result of a process by which surface waters loose buoyancy due to  
73 atmospheric forcing and sink into the interior of the ocean. It occurs only where specific conditions  
74 are met including large air-sea buoyancy loss and favorable preconditioning (i.e. low stratification of  
75 the water column) (Marshall & Schott, 1999). In the Subpolar North Atlantic (SPNA), deep convection  
76 takes place in the Labrador Sea, South of Cape Farewell and in the Irminger Sea (Kieke & Yashayaev,  
77 2015; Pickart et al. 2003; Piron et al. 2017). Deep convection connects the upper and lower limbs of  
78 the Meridional Overturning Circulation (MOC) and transfers climate change signals from the surface  
79 to the ocean interior.

80 Observing deep convection is difficult because it happens on short time and small spatial scales and  
81 during periods of severe weather conditions (Marshall & Schott, 1999). The onset of the Argo  
82 program at the beginning of the 2000s has considerably increased the number of available  
83 oceanographic data throughout the year. Although the sampling characteristics of Argo are not  
84 adequate to observe the small scales associated with the convection process itself, Argo data allow  
85 the description of the overall intensity of the event and the characterization of the properties of the  
86 water masses formed in the winter mixed layer as well (e.g., Yashayaev and Loder, 2017).

87 In the Labrador Sea, deep convection occurs every year, yet with different intensity (e.g., Yashayaev  
88 and Clarke, 2008; Kieke and Yashayaev, 2015). In the Irminger Sea, Argo and mooring data showed  
89 that convection deeper than 700 m happened during winters 2008, 2009, 2012, 2015 and 2016 (Väge  
90 et al., 2009; de Jong et al., 2012; Piron et al. 2015; de Jong & de Steur, 2016; Fröb et al., 2016; Piron  
91 et al. 2017; de Jong et al., 2018). Moreover, in winter 2015, deep convection was also observed south  
92 of Cape Farewell (Piron et al., 2017). Excluding winter 2009 when the deep convection event was  
93 made possible thanks to a favorable preconditioning (de Jong et al., 2012), all events coincided with  
94 strong atmospheric forcing (air-sea heat loss). Prior to 2008, only few deep convection events were  
95 reported because the mechanisms leading to it were not favorable (Centurioni and Gould, 2004) or  
96 because the observing system was not adequate (Bacon, 1997; Pickart et al., 2003). Nevertheless, the  
97 hydrographic properties from the 1990s suggested that deep convection reached as deep as 1,500 m  
98 in the Irminger Sea during winters 1994 and 1995 (Pickart et al., 2003), and as deep as 1,000 m south  
99 of Cape Farewell during winter 1997 (Bacon et al., 2003).

100 The convection depths that were reached in the Irminger Sea and south of Cape Farewell at the end  
101 of winter 2015 were the deepest observed in these regions since the beginning of the 21<sup>st</sup> century  
102 (de Jong et al., 2016; Piron et al., 2017, Fröb et al., 2016). In this work, we show that deep convection

103 also happened in a region between south of Cape Farewell and the Irminger Sea (the pink box in  
104 Figure 1) every winter from 2016 to 2018. Hereinafter, we will refer to this region as Southeast Cape  
105 Farewell (SECF). We investigated the respective role of atmospheric forcing (air-sea buoyancy flux)  
106 and preconditioning (ocean interior buoyancy content) in setting the convection intensity. We also  
107 disentangled the relative contribution of salinity and temperature anomalies to the preconditioning.  
108 The paper is organized as follow. The data are described in Sect. 2. The methodology is explained in  
109 Sect. 3. We expose our results in Sect. 4 and discuss them in Sect. 5. Conclusions are listed in Sect. 6.

110

## 111 **2. DATA**

112 We used temperature (T), salinity (S) and pressure (P) data measured by Argo floats north of 55°N in  
113 the Atlantic Ocean. These data were collected by the International Argo program  
114 (<http://www.argo.ucsd.edu/>), <http://www.jcommops.org/>) and downloaded from the Coriolis Data  
115 Center (<http://www.coriolis.eu.org/>). Only data flagged as good (quality Control < 3, Argo Data  
116 Management Team, 2017) were considered in our analysis. Potential temperature ( $\theta$ ), density ( $\rho$ )  
117 and potential density anomaly referenced to the surface and 1000 dbar ( $\sigma_0$  and  $\sigma_1$ , respectively) were  
118 estimated from T, S and P data using TEOS-10 (<http://www.teos-10.org/>).

119 We used two different gridded products of ocean T and S: ISAS and EN4. ISAS (Gaillard et al., 2016;  
120 Kolodziejczyk et al., 2017) is produced by optimal interpolation of *in situ* data. It provides monthly  
121 fields, at 152 depth levels, at 0.5° resolution, from 2002 to 2015. Near real time data are also  
122 available for 2016 and 2018. EN4 (Good et al., 2013) is an optimal interpolation of *in situ* data; it  
123 provides monthly T and S at 1° spatial resolution and at 42 depth levels, for the period 1900 to  
124 present.

125 Net air-sea heat flux (Q, the sum of radiative and turbulent fluxes), evaporation (E), precipitation (P),  
126 wind stress ( $\tau_x$  and  $\tau_y$ ) and sea surface temperature (SST) data were obtained from ERA-Interim  
127 reanalysis (Dee et al., 2011). ERA-Interim provides data with a time resolution of 12h and a spatial  
128 resolution of 0.75°, respectively. The air-sea freshwater flux (FWF) was estimated as E - P.

129 We used monthly Absolute Dynamic Topographic (ADT), which was computed from the daily 0.25° -  
130 resolution ADT data provided by CMEMS (Copernicus Marine and Environment Monitoring Service,  
131 <http://www.marine.copernicus.eu>).

132

## 133 **3. METHODS**

134 3.1 Quantification of the deep convection

135 We characterized the convection in the SPNA in winters 2015-2018 by estimating the mixed layer  
136 depths (MLD) for all Argo profiles collected in the SPNA north of 55°N from 1<sup>st</sup> January to 30<sup>th</sup> April of  
137 each year (Fig. 1). The MLD was estimated as the shallowest of the three MLD estimates obtained by  
138 applying the threshold method (de Boyer Montégut et al., 2004) to  $\theta$ , S and  $\rho$  profiles separately. The  
139 threshold method computes the MLD as the depth at which the difference between the surface (30  
140 m) and deeper levels in a given property is equal to a given threshold. In case visual inspection of the  
141 winter profiles showed a thin stratified layer at the surface, a slightly deeper level (<150 m) was  
142 considered as surface reference level. Following Piron et al. (2017), this threshold was taken equal to  
143 0.01 kg m<sup>-3</sup> for  $\rho$ . For  $\theta$  and S, we selected thresholds of 0.1°C and 0.012 respectively because they  
144 correspond to the threshold of 0.01 kg m<sup>-3</sup> in  $\rho$ . The latter was previously shown to perform well in  
145 the subpolar gyre on density profiles (Piron et al., 2016). Our MLD estimates are comparable to those  
146 obtained using MLD determination based on Pickart et al. (2002)'s and de Jong et al. (2012)'s  
147 methods (see section S1, Fig. S1 and Fig. S2 in supplementary material).

148 In this paper, deep convection is characterized by profiles with MLD deeper than 700m (colored  
149 points in Fig. 1) because it is the minimum depth that should be reached for renewing Labrador Sea  
150 Water (LSW) (Yashayaev et al., 2007; Piron et al. 2016). The winter MLD and the associated  $\theta$ , S and  $\rho$   
151 properties were examined for the Labrador Sea and the SECF region by considering the profiles inside  
152 the cyan and pink boxes in Fig. 1, respectively. Those two boxes were defined to include all Argo  
153 profiles with MLD deeper than 700 m during 2016 – 2018 and the minimum of the monthly ADT for  
154 either the SECF region or the Labrador Sea. No deep MLD was recorded in the northernmost part of  
155 the Irminger Sea during this period. We computed the maximum MLD and the MLD third quartile  
156 ( $Q_3$ ) from profiles with MLD greater than 700m in each of the two boxes separately.  $Q_3$  is the MLD  
157 value that is exceeded by 25% of the profiles and is equivalent to the aggregate maximum depth of  
158 convection defined by Yashayaev and Loder (2016). The properties ( $\rho$ ,  $\theta$  and S) of the mixed layers  
159 were defined for each winter as the vertical mean from 200 m to the MLD of all profiles with MLD  
160 deeper than 700 m. For further use, we define the deep convection period as follows. For a given  
161 winter, the deep convection period begins the day when the first profile with a deep (>700m) mixed  
162 layer is detected and ends the day of the last detection of a deep mixed layer.

163 3.2. Time series of atmospheric forcing

164 The air-sea buoyancy flux ( $B_{\text{surf}}$ ) was calculated as the sum of the contributions of Q and FWF (Gill,  
165 1982; Billheimer & Talley, 2013). It reads:

166  $B_{surf} = \frac{\alpha g}{\rho_0 c_p} Q - \beta g SSS FWF$  Eq. (1)

167 Where  $\alpha$  and  $\beta$  are the coefficients of thermal and saline expansions, respectively, estimated from  
 168 surface T and S. The gravitational acceleration  $g$  is equal to  $9.8 \text{ m s}^{-2}$ , the reference density of sea  
 169 water  $\rho_0$  is equal to  $1026 \text{ kg m}^{-3}$  and heat capacity of sea water  $C_p$  is equal to  $3990 \text{ J kg}^{-1} \text{ }^{\circ}\text{C}^{-1}$ . SSS is  
 170 the sea surface salinity. Q and FWF are in  $\text{W m}^{-2}$  and  $\text{m s}^{-1}$ , respectively.

171 For easy comparison with previous results, which only considered the heat component of the  
 172 buoyancy air-sea flux (e.g. Yashayaev & Loder, 2017; Piron et al. 2017; Rhein et al., 2017),  $B_{surf}$ , in  $\text{m}^2$   
 173  $\text{s}^{-3}$ , was converted to  $\text{W m}^{-2}$  following Eq. (2) and noted  $B_{surf}^*$

174  $B_{surf}^* = \frac{\rho_0 c_p}{g \alpha} B_{surf}$  Eq. (2)

175 The FWF was also converted to  $\text{W m}^{-2}$  using:

176  $\text{FWF}^* = \text{FWF} \beta SSS \frac{\rho_0 c_p}{\alpha}$  Eq. (3)

177 We also computed the horizontal Ekman buoyancy flux ( $BF_{ek}$ ), which can be decomposed into the  
 178 horizontal Ekman heat flux ( $HF_{ek}$ ) and salt flux ( $SF_{ek}$ ). Noting :

179  $BF_{ek} = -g (U_e \partial_x SSD + V_e \partial_y SSD) \frac{c_p}{\alpha g}$  Eq. (4)

180  $HF_{ek} = -(U_e \partial_x SST + V_e \partial_y SST) \rho_0 C_p$  Eq. (5)

181  $SF_{ek} = -(U_e \partial_x SSS + V_e \partial_y SSS) \frac{\beta \rho_0 c_p}{\alpha}$  Eq. (6)

182  $BF_{ek} = SF_{ek} - HF_{ek}$ .  $U_e$  and  $V_e$  are the eastward and northward components of the Ekman horizontal  
 183 transport estimated from the wind stress meridional and zonal components. SSD, SST and SSS are  $\rho$ ,  
 184 T and S at the surface of the ocean.  $BF_{ek}$ ,  $HF_{ek}$  and  $SF_{ek}$  are in  $\text{J s}^{-1} \text{ m}^{-2}$ . Because ERA-Interim does not  
 185 supply SSD or SSS, they were estimated from EN4 as follows. The monthly T and S data at 5 m depth  
 186 from EN4 were interpolated on the same time and space grid as the air-sea fluxes from ERA-Interim  
 187 (12h and  $0.75^{\circ}$ , respectively). SSD was estimated from those interpolated EN4 data (SST and SSS).  
 188 Properties at 5 m depth were considered to be representative of the Ekman layer. Data at locations  
 189 where ocean bottom was shallower than 1000 m were excluded from the analysis to avoid regions  
 190 covered by sea-ice.

191 Following Piron et al. (2016), the time series of atmospheric forcing were estimated for the SECF  
 192 region and the Labrador Sea as follows. First, the gridded air-sea flux data and the horizontal Ekman

193 fluxes were averaged over the pink (SECF region) and cyan (Labrador Sea) boxes (Fig. 1). Second, we  
194 estimated the accumulated fluxes from 1 September to 31 August the year after. Finally, we  
195 computed the time series of the anomalies of the accumulated fluxes from 1 September to 31 August  
196 with respect to the 1993 – 2016 mean.

197 Finally, in order to quantify the net intensity of the atmospheric forcing over the winter, we  
198 computed estimates of  $B_{\text{surf}}^* + BF_{\text{ek}}$  fluxes accumulated from 1 September to 31 March the year after.  
199 Following Piron et al. (2017), the associated errors were calculated by a Monte Carlo simulation using  
200 50 random perturbations of  $Q$ , FWF and  $B_{\text{surf}}$ . The error amounted to 0.05, 0.04 and 0.03  $\text{J m}^{-2}$  for  
201  $B_{\text{surf}}^*$ ,  $Q$  and FWF\*, respectively. The error of the horizontal Ekman buoyancy transport was also  
202 estimated by a Monte Carlo simulation and amounted to 0.04  $\text{J m}^{-2}$ .

### 203 3.3. Preconditioning of the water column

204 The preconditioning of the water column was evaluated as the buoyancy that has to be removed  
205 ( $B(z_i)$ ) from the late summer density profile to homogenize it down to a depth  $z_i$ . It reads:

$$206 B(z_i) = \frac{g}{\rho_0} \sigma_0(z_i) z_i - \frac{g}{\rho_0} \int_{z_i}^0 \sigma_0(z) dz \quad \text{Eq. (7)}$$

207  $\sigma_0(z)$  is the vertical profile of potential density anomaly estimated from the profiles of T and S  
208 measured by Argo floats in September in the given region (pink or cyan box in Fig. 1).

209 Following Schmidt and Send (2007), we split  $B$  into a temperature ( $B_\theta$ ) and salinity ( $B_S$ ) term:

$$210 B_\theta(z_i) = -\left(g \alpha \theta(z_i) z_i - g \alpha \int_{z_i}^0 \theta(z) dz\right) \quad \text{Eq. (8)}$$

$$211 B_S(z_i) = g \beta S(z_i) z_i - g \beta \int_{z_i}^0 S(z) dz \quad \text{Eq. (9)}$$

212 In order to compare the preconditioning with the heat to be removed and/or air-sea heat fluxes,  $B$ ,  
213  $B_\theta$  and  $B_S$  are reported in  $\text{J m}^{-2}$ .  $B$ ,  $B_\theta$  and  $B_S$  were estimated for a given year from the mean of all  
214 September profiles of  $B$ ,  $B_\theta$  and  $B_S$ . The associated errors were estimated as  $\text{std}(B)/\sqrt{n}$ , where  $n$  is  
215 the number of profiles used to compute the September mean values.

216

## 217 4. RESULTS

### 218 4.1. Intensity of deep convection and properties of newly formed LSW

219 We examine the time-evolution of the winter mixed layer SECF since the exceptional convection  
220 event of winter 2015 (W2015 hereinafter) (Table 1 and Figs. 1 - 3). In W2015, we recorded a  
221 maximum MLD of 1,710 m south of Cape Farewell (Fig. 1a), in line with Piron et al. (2017). The  
222 maximum MLD of 1,575 m observed for W2016 (Fig. 1b) is compatible with the MLD > 1,500 m  
223 observed in a mooring array in the central Irminger Sea by de Jong et al. (2018). For W2015 and  
224 W2016, Q3 was 1,205 m and 1,471 m, respectively (Table 1). In W2017, deep convection was  
225 observed from three Argo profiles (Fig. 1c and Fig. 2a-c). The maximum MLD of 1,400 m was  
226 observed on 16<sup>th</sup> March 2017 at 56.65°N – 42.30°W. In W2018, the maximum MLD of 1,300 m was  
227 observed on 24 February at 58.12°N, 41.84°W (Fig. 1d, 2d-f). Float 5903102 measured MLD of 1,100  
228 m South of Cape Farewell (Fig. 1d), but the estimated MLDs coincided with the deepest levels of  
229 measurement of the float so that these estimates, possibly biased low (see Fig. 2d-f), were discarded  
230 from our analysis. These results show that convection deeper than 1,300 m occurred during four  
231 consecutive winters SECF.

232 Although the number of floats showing deep convection in W2017 and W2018 was small (3 and 2  
233 floats), it represented a significant percentage of the floats operating in the SECF box at that time.  
234 The percentage of floats showing deep convection in the SECF region was computed for the deep  
235 convection periods defined from 15 January 2015 to 21 April 2015, 22 February 2016 to 21 March  
236 2016, 16 March 2017 to 4 April 2017 and 24 February 2018 to 26 March 2018. The longest period of  
237 deep convection occurred in W2015, the shortest in 2017. The percentage of floats showing deep  
238 convection during the deep convection period are 73%, 50%, 33 % and 50%, for winters 2015, 2016,  
239 2017 and 2018, respectively. The lowest % is found for W2017, but it is still substantial. It might  
240 reflect that for this specific year floats showing deep MLD were found in the southwestern corner of  
241 the SECF box only, suggesting that convection did not occur over the full box.

242 The properties ( $\sigma_0$ , S and  $\theta$ ) of the end of winter mixed layer were estimated for the four winters  
243 (Table 1 and Fig. 3). We observed that, between W2015 and W2018, the water mass formed by deep  
244 convection significantly densified and cooled by  $0.019 \text{ kg m}^{-3}$  and  $0.215^\circ\text{C}$ , respectively (see Table 1  
245 and Fig. 3).

246 In the Labrador Sea, Q3 increased from 2015 to 2018 (see Table 1). Deep convection observed in the  
247 Labrador Sea in W2018 was the most intense since the beginning of the Argo era (see Fig. 2c in  
248 Yashayaev & Loder, 2016). From W2015 to W2018, newly formed LSW cooled, became saltier and  
249 densified by  $0.134^\circ\text{C}$ ,  $0.013$  and  $0.023 \text{ kg m}^{-3}$ , respectively (Table 1).

250 The water mass formed SECF is warmer and saltier than that formed in the Labrador Sea (Fig. 3). The  
251 deep convection SECF is always shallower than in the Labrador Sea. This result is discussed later in  
252 Sect. 5.

#### 253 4.2. Analysis of the atmospheric forcing Southeast of Cape Farewell

254 The seasonal cycles of  $B_{surf}^*$  and  $Q$  are in phase and of the same order of magnitude, while  $FWF^*$ ,  
255 which is positive and one order of magnitude lower than  $Q$ , does not present a seasonal cycle (Fig.  
256 S3). The means (1993 – 2018) of the cumulative sums from 1 September to 31 March of  $Q$ ,  $FWF^*$  and  
257  $B_{surf}^*$  estimated over the SECF box (Fig. 1) are  $-2.46 \pm 0.43 \times 10^9 \text{ J m}^{-2}$ ,  $0.28 \pm 0.10 \times 10^9 \text{ J m}^{-2}$  and  $-$   
258  $2.22 \pm 0.49 \times 10^9 \text{ J m}^{-2}$ , respectively. Despite  $B_{surf}^*$  is mainly explained by  $Q$ , the accumulated  $FWF^*$   
259 amounts to  $\sim 10\%$  of the accumulated  $Q$  with opposite sign. The air-sea buoyancy flux is 10% lower  
260 on average than the air-sea heat flux. Considering the Ekman transports, the 1993 – 2018 means of  
261 the accumulated  $BF_{ek}$ ,  $HF_{ek}$  and  $SF_{ek}$  from 1 September to 31 March amount to  $0.37 \pm 1.15 \times 10^8 \text{ J m}^{-2}$ ,  
262  $-0.35 \pm 1.36 \times 10^8 \text{ J m}^{-2}$ , and  $0.02 \pm 2.04 \times 10^8 \times 10^9 \text{ J m}^{-2}$ , respectively. The horizontal Ekman heat  
263 flux is negative, while the Ekman buoyancy flux is positive. This buoyancy gain indicates a  
264 southeastward transport of surface freshwater caused by dominant winds from the southwest.  
265 Noteworthy,  $BF_{ek}$  is one order of magnitude smaller than the  $B_{surf}^*$ .

266 The total atmospheric forcing SECF was quantified as the sum of  $B_{surf}^*$  and  $BF_{ek}$ . The anomalies of  
267 accumulated fluxes from 1 September to 31 August the year after, with respect to the mean 1993 –  
268 2016, are displayed in Fig. 4 for the SECF box. The grey line in Fig. 4a is the total atmospheric forcing  
269 anomaly ( $B_{surf}^*$  plus  $BF_{ek}$ ). We identify years with very negative buoyancy loss in the SECF region, e.g.  
270 1994, 1999, 2008, 2012 and 2015. The very negative anomalies of atmospheric forcing in 1999 and  
271 2015 were caused by the very negative anomalies in both  $B_{surf}^*$  (Fig. 4a) and  $BF_{ek}$  (Fig. 4d). This  
272 correlation was not observed for all the years presenting a negative anomaly of atmospheric forcing.  
273 Noteworthy, during W2016, W2017 and W2018, the anomaly of atmospheric forcing was close to  
274 zero.

275 Contrary to the very negative anomaly in atmospheric fluxes over the SECF region observed for  
276 W2015, the atmospheric fluxes were close to the mean during W2016, W2017 and W2018.

#### 277 4.3. Analysis of the preconditioning of the water column Southeast of Cape 278 Farewell

279 Our hypothesis is that the exceptional deep convection that happened in W2015 in the SECF region  
280 favorably preconditioned the water column for deep convection the following winters. The time-

281 evolutions of  $\theta$ ,  $S$ ,  $\sigma_1$  and of  $\Delta\sigma_1=0.01 \text{ kg m}^{-3}$  layer thicknesses (Fig. 5) show a marked change in the  
282 hydrographic properties of the SECF region at the beginning of 2015 caused by the exceptional deep  
283 convection that occurred during W2015 (see Piron et al., 2017). The intermediate waters (500 –  
284 1,000 m) became colder than the years before and, despite a slight decrease in salinity, the cooling  
285 caused the density to increase (Fig. 5c). Fig. 5d shows  $\Delta\sigma_1=0.01 \text{ kg m}^{-3}$  layer thicknesses larger than  
286 600 m appearing at the end of W2015 for the first time since 2002. In the density range 32.36 – 32.39  
287  $\text{kg m}^{-3}$ , these layers remained thicker than ~450 m during W2016 to W2018. This indicates low  
288 stratification at intermediate depths and a favorable preconditioning of intermediate waters for deep  
289 convection initiated by W2015 deep convection. The denser density of the core of the thick layers in  
290 2017 -2018 compared with 2015 - 2016 agrees with the densification of the mixed layer SECF shown  
291 in Table 1 and Fig. 3.

292  $B(z)$  is our estimate of the preconditioning of the water column before winter (see Method). Fig. 6a  
293 shows that, deeper than 100 m,  $B$  for W2016, W2017 and W2018 was smaller than  $B$  for W2015 or  $B$   
294 for the mean W2008 – W2014. Furthermore, for W2016, W2017 and 2018,  $B$  remained nearly  
295 constant with depth between 600 and 1,300 m, which means that once the water column has been  
296 homogenized down to 600 m, little additional buoyancy loss results in the homogenization of the  
297 water column down to 1,300 m. Both conditions (i) less buoyancy to be removed and (ii) absence of  
298 gradient in the  $B$  profile down to 1,300 m indicate a more favorable preconditioning of the water  
299 column for W2016, W2017 and W2018 than during W2008 – W2015.

300 To understand the relative contributions of  $\theta$  and  $S$  to the preconditioning, we computed the thermal  
301 ( $B_\theta$ ) and haline ( $B_s$ ) components of  $B$  ( $B = B_\theta + B_s$ ). In general,  $B_\theta$  ( $B_s$ ) increases with depth when  $\theta$   
302 decreases ( $S$  increases) with depth. On the contrary, a negative slope in a  $B_\theta$  ( $B_s$ ) profile corresponds  
303 to  $\theta$  increasing ( $S$  decreasing) with depth and is indicative of a destabilizing effect. The negative  
304 slopes in  $B_\theta$  and  $B_s$  profiles are not observed simultaneously because density profiles are stable.

305 We describe the relative contributions of  $B_\theta$  and  $B_s$  to  $B$  by looking first at the mean 2008 – 2014  
306 profiles (discontinuous blue lines in Fig. 6).  $B_\theta$  accounts for most of the increase in  $B$  from the surface  
307 to 800 m and below 1,400 m (see Fig. 6a and Fig. 6b). The negative slope in the  $B_s$  profile between  
308 800 – 1,000 m (Fig. 6c) slightly reduces  $B$  (Fig. 6a) and is due to the decrease in  $S$  associated with the  
309 core of LSW (see Fig. 3 in Piron et al. 2016). In the layer 1,000 – 1,400 m, the increase in  $B$  (Fig. 6a) is  
310 mainly explained by the increase in  $B_s$  (Fig. 6c), which follows the increase in  $S$  in the transition from  
311 LSW to Iceland Scotland Overflow Water (ISOW). This transition layer will be referred to hereinafter  
312 as the deep halocline. The evaluation of the preconditioning of the water column was usually  
313 analyzed in terms of heat (e.g., Piron et al. 2015; 2017). The decomposition of  $B$  in  $B_\theta$  and  $B_s$  reveals

314 that  $\theta$  governs  $B$  in the layer 0 – 800 m.  $S$  tends to reduce the stabilizing effect of  $\theta$  in the layer 800 –  
315 1,000 m, and reinforces it in the layer 1,000 – 1,400 m by adding up to  $1 \times 10^9 \text{ J m}^2$  to  $B$ .

316 In order to further understand why the SEFC region was favorably preconditioned during winters  
317 2016 – 2018, we compare the  $B_\theta$  and  $B_s$  of W2017, which was the most favorably preconditioned  
318 winter, with the mean 2008 – 2014 (Fig. 7a). From the surface to 1,600 m,  $B_\theta$  and  $B_s$  were smaller for  
319 W2017 than for the mean 2008 – 2014. There are two additional remarkable features. First, in the  
320 layer 500 – 1000 m, the large reduction of  $B_\theta$  compared to the 2008 – 2014 mean, mostly explains  
321 the decrease in  $B$  in this layer. Second, the more negative value of  $B_s$  in the layer 1,100 – 1,300 m,  
322 compared to the 2008 – 2014 mean, eroded the  $B_\theta$  slope, making the  $B$  profile more vertical for  
323 W2017 than for the mean. The more negative contribution of  $B_s$  in the layer 1,100 – 1,300 m comes  
324 from the fact that the deep halocline was deeper for W2017 (1,300 m, see orange dashed line in Fig.  
325 7a) than for the mean 2008 – 2014 (1,000 m, see blue dashed line in Fig. 7a). Finally, we note that the  
326 profiles of  $B(z_i)$ ,  $B_\theta(z_i)$  and  $B_s(z_i)$  for W2016 and W2018 are more similar to the profiles of W2017 than  
327 to those of W2015 or to the mean 2008 – 2014 (see Fig. 6), which indicates that the water column  
328 was also favorably preconditioned for deep convection in W2016 and W2018 for the same reasons as  
329 in W2017.

330 The origin of the changes in  $B$  is now discussed from the time evolutions of the monthly anomalies of  
331  $\theta$ ,  $S$  and  $\sigma_0$  at  $58^\circ\text{N} - 40^\circ\text{W}$  that is at the center of the SECF box (Fig. 8). The time evolutions there are  
332 similar to those at any other location inside the SECF box. These anomalies were computed using  
333 ISAS (Gaillard et al., 2016) and were referenced to the monthly mean of 2002 – 2016. A positive  
334 anomaly of  $\sigma_0$  appeared in 2014 between the surface and 600 m (Fig. 8a) and reached 1,200m in  
335 2015 and beyond. This positive anomaly of  $\sigma_0$  correlates with a negative anomaly of  $\theta$ . The latter,  
336 however, reached  $\sim 1,400$  m depth in 2016 that is deeper than the positive anomaly of  $\sigma_0$ . The  
337 negative anomaly of  $S$  between 1,000 - 1,500 m that appeared in 2015 and strongly reinforced in  
338 2016 caused the negative anomaly in  $\sigma_0$  between 1,200 – 1,500 m (the density anomaly caused by  
339 the negative anomaly in  $\theta$  between 1,200 – 1,400 m does not balance the density anomaly caused by  
340 the negative anomaly of  $S$ ).

341 The  $\theta$  and  $S$  anomalies in the water column during 2016 – 2018 explain the anomalies of  $B$ ,  $B_\theta$  and  $B_s$   
342 and can be summarized as follows. On the one hand, the properties of the surface waters (down to  
343 500 m) were colder than previous years and, despite they were also fresher, they were denser. The  
344 density increase in the surface water reduced the density difference with the deeper-lying waters.  
345 The intermediate layer (500 – 1000 m) was also favorably preconditioned due to the observed  
346 cooling. Additionally, in the layer 1,100 – 1,300 m, the large negative anomaly of  $B_s$  with respect to its

347 mean is explained by the decrease in S in this layer, which caused a decrease in  $\sigma_0$  and, consequently,  
348 reduced the  $\sigma_0$  difference with the shallower-lying water. The decrease in S also resulted in a  
349 deepening of the deep halocline.

350 **4.4. Atmospheric forcing versus preconditioning of the water column**

351 We now use the estimates of the accumulated atmospheric forcing ( $B_{\text{surf}}^* + BF_{\text{ek}}$ ) from 1 September  
352 to 31 March the year after (see Fig. S4) to predict the maximum convection depth for a given winter  
353 based on September profiles of B. The predicted convection depth is determined as the depth at  
354 which  $B(z)$  (Fig. 6a) equals the accumulated atmospheric forcing. The associated error was estimated  
355 by propagating the error in the atmospheric forcing ( $0.05 \times 10^9 \text{ J m}^{-2}$ ). The accumulated atmospheric  
356 forcing amounted to  $-3.21 \times 10^9 \pm 0.05 \text{ J m}^{-2}$ ,  $-2.21 \pm 0.04 \times 10^9 \text{ J m}^{-2}$ ,  $-2.01 \pm 0.05 \times 10^9 \text{ J m}^{-2}$  and  $-2.47$   
357  $\pm 0.05 \times 10^9 \text{ J m}^{-2}$  for W2015, W2016, W2017 and W2018, respectively. We found predicted  
358 convection depths of  $1,085 \pm 20 \text{ m}$ ,  $1,285 \pm 20 \text{ m}$ ,  $1,415 \pm 20 \text{ m}$  and  $1,345 \pm 20 \text{ m}$  for W2015, W2016,  
359 W2017 and W2018, respectively. We consider Q3 as the observed estimate of the MLD (Table 1). The  
360 predicted MLD agrees with the observed MLD within  $\pm 200 \text{ m}$ . The differences could be due to errors  
361 in the atmospheric forcing (Josey et al., 2018), lateral advection and/or spatial variation in the  
362 convection intensity within the box not captured by the Argo sampling.

363 The satisfactory predictability of the convection depth with our 1-D model indicates that deep  
364 convection occurred locally. In spite the atmospheric forcing was close to mean (1993 – 2016)  
365 conditions during W2016, W2017 and W2018, convection depths  $> 1300 \text{ m}$  were reached in the SECF  
366 region. This was only possible thanks to the favorable preconditioning.

367

368 **5. DISCUSSION**

369 Deep convection happens in the Irminger Sea and South of Cape Farewell during specific winters  
370 characterized by a strong atmospheric forcing (high buoyancy loss), a favorable preconditioning (low  
371 stratification) or both at the same time (Bacon et al., 2003; Pickart et al., 2003). In the Irminger Sea,  
372 strong atmospheric forcing explained for instance the very deep convection (reaching depth greater  
373 than 1,500 m) observed in the early 90s (Pickart, et al., 2003) and in W2015 (de Jong et al. 2016; Fröb  
374 et al., 2016; Piron et al. 2017). It explained as well the return of deep convection in W2008 (Väge et  
375 al., 2009) and in W2012 (Piron et al., 2016). The favorable preconditioning caused by the  
376 densification of the mixed layer during W2008 favored a new deep convection event in W2009  
377 despite neutral atmospheric forcing (de Jong et al. 2012). Similarly, the preconditioning observed  
378 after W2015 in the SECF region favored deep convection in W2016 (this work). The favorable  
379 preconditioning persisted three consecutive winters (2016 – 2018) in the SECF region, which allowed

380 deep convection although atmospheric forcing was close to the climatological values. Why did this  
381 favorable preconditioning persist in time?

382 We previously showed that during 2016 – 2018 two hydrographic anomalies affected different  
383 ranges of the water column in SECF box: a cooling intensified in the layer 200 – 800 m and a  
384 freshening intensified in 1,000 – 1,500 m layer. Those resulted in a decrease in the vertical density  
385 gradient between the intermediate and the deeper layers creating a favorable preconditioning of the  
386 water column. Note that the cooling affected the layer from surface to 1,400 m and the freshening  
387 affected the layer from near surface to 1,600 m, but the cooling and the freshening were intensified  
388 at different depth ranges (Fig. 8).

389 We see in Fig. 5a a sudden decrease in  $\theta$  in the intermediate layers in 2015 compared to the previous  
390 years. It indicates that the decrease in  $\theta$  of the intermediate layer likely originated locally during  
391 W2015 when extraordinary deep convection happened. A slight freshening of the water column  
392 (400- 1,500 m) appeared in 2015, likely caused by the W2015 convection event, then it decreased  
393 before a second S anomaly intensified in 2016 between 1,100 and 1,400 m (Fig. 8c). It is unlikely that  
394 this second anomaly was exclusively locally formed by deep convection because it intensified during  
395 summer 2016. Our hypothesis is that this second S anomaly originated in the Labrador Sea and was  
396 further transferred to the SECF region by the cyclonic circulation encompassing the Labrador Sea and  
397 Irminger Sea at these depths (Daniault et al., 2016; Ollitrault & Colin de Verdière, 2014; Lavander et  
398 al., 2000 ; Straneo et al., 2003). It is corroborated by the 2D evolution of the anomalies in S in the  
399 layer 1,200 – 1,400 m (Fig. 9): a negative anomaly in S appeared in the Labrador Sea in February  
400 2015, which was transferred southward and northeastward in February 2016 and intensified over the  
401 whole SPNA in February 2017. By this mechanism, the advection from the Labrador Sea contributed  
402 to create property anomalies in the water column. However, the buoyancy budget showed that this  
403 was a minor contribution compared to the buoyancy loss due to the local air-sea flux, even if it was  
404 essential to preconditioning the water column for deep convection.

405 We now compare the atmospheric forcing and the preconditioning of the water column in the SECF  
406 region with those of the nearby Labrador Sea where deep convection happens almost every year.  
407 The atmospheric forcing over the Labrador Sea is  $\sim 15$  % larger than that over the SECF region: the  
408 means (1993 - 2018) of the atmospheric forcing, defined as the time accumulated  $B_{\text{surf}}^* + BF_{\text{ek}}$  from 1  
409 September to 31 March the year after, are  $-2.61 \pm 0.55 \times 10^9 \text{ J m}^{-2}$  in the Labrador Sea and  $-2.18 \pm$   
410  $0.54 \times 10^9 \text{ J m}^{-2}$  in the SECF region. The difference was larger during the period 2016 – 2018 when the  
411 atmospheric forcing equaled  $-3.10 \pm 0.19 \times 10^9 \text{ J m}^{-2}$  in the Labrador Sea and  $-2.23 \pm 0.23 \times 10^9 \text{ J m}^{-2}$  in  
412 the SECF region. In terms of preconditioning, the 2008 – 2014 mean B profile (blue continuous lines

413 in Fig. 7) was lower by  $\sim 0.5 \times 10^9 \text{ J m}^{-2}$  in the Labrador Sea than SECF for the surface to 1,000 m layer  
414 and by more than  $1 \times 10^9 \text{ J m}^{-2}$  below 1,200 m. It indicates that the water column was more favorably  
415 preconditioned in the Labrador Sea than in the SECF region during 2008 – 2014. Differently, B for  
416 W2017 shows slightly lower values from the surface to 1,300 m in the SECF region than in the  
417 Labrador Sea (see orange lines in Fig. 7). However, B in the Labrador Sea remains constant down to  
418 the depth of the deep halocline between LSW and North Atlantic Deep Water (NADW) at 1,700 m. In  
419 the SECF region, the deep halocline remained at  $\sim 1,300 \text{ m}$  between 2016 and 2018 (see  $B_s$  lines in  
420 Fig. 7a). Differently, in the Labrador Sea, the deep halocline deepened from 1,200 m for the mean to  
421 1,735 m, 1,775 m and 1905 m in W2016, W2017 and W2018, respectively (see dashed lines in Fig.  
422 7b). The deep halocline acts as a physical barrier for deep convection in both the SECF region and the  
423 Labrador Sea, but because the deep halocline is deeper in the Labrador Sea than in SECF region, the  
424 preconditioning is more favorable to a deeper convection in the Labrador Sea than in the SECF  
425 region. Summarizing, in winters 2016 - 2018 in the Labrador Sea, both atmospheric forcing and  
426 preconditioning of the water column granted the deepest convection depth in the Labrador Sea since  
427 the beginning of the Argo period (comparison of our results with those of Yashayaev and Loader,  
428 2017). Contrasting, in SECF region, during the same period, the atmospheric forcing was close to  
429 climatological values, and the favorable preconditioning of the water column allowed 1,300 m depth  
430 convection, what was exceptional for the SECF region.

431 The Labrador Sea, SECF region and Irminger Sea are three distinct deep convection sites (e.g.  
432 Yashayaev et al., 2007; Bacon et al., 2003; Pickart et al., 2003; Piron et al., 2017). In this work, we  
433 give new insights on the connections between the different sites, showing how lateral advection of  
434 fresh LSW formed in the Labrador Sea favored the preconditioning in the SECF region fostering  
435 deeper convection.

436 Climate models forecast increasing input of freshwater in the North Atlantic due to ice-melting under  
437 present climate change (Bamber et al., 2018), which could reduce, or even shut-down, the deep  
438 convection in the North Atlantic (Yang et al., 2016; Brodeau & Koenigk, 2016). We observed a fresh  
439 anomaly in the surface waters in regions close to the eastern coast of Greenland in 2016 that  
440 extended to the whole Irminger Sea in 2017 (Fig. S6). However, this surface freshening did not  
441 hamper the deep convection in the SECF region possibly because the surface water also cooled.  
442 Swingedouw et al., 2013 indicated that the freshwater signal due to Greenland ice sheet melting is  
443 mainly accumulating in the Labrador Sea. However, no negative anomaly of S was detected in the  
444 surface waters of the Labrador Sea (Fig. S6). It might be explained by the intense deep convection  
445 affecting the Labrador Sea since 2014 that could have transferred the surface freshwater anomaly to  
446 the ocean interior. This suggests that, in the last years, the interactions between expected climate

447 change anomalies and the natural dynamics of the system combined to favor very deep convection.  
448 This however does not foretell the long term response to climate change.

449

## 450 **6. CONCLUSIONS**

451 During 2015 – 2018 winter deep convection happened in the SECF region reaching deeper than 1,300  
452 m. It is the first time deep convection was observed in this region during four consecutive winters.

453 The atmospheric forcing and preconditioning of the water column was evaluated in terms of  
454 buoyancy. We showed that the atmospheric forcing is 10% weaker when evaluated in terms of  
455 buoyancy than in terms of heat because of the non-negligible effect of the freshwater flux. The  
456 analysis of the preconditioning of the water column in terms of buoyancy to be removed (B) and its  
457 thermal and salinity terms ( $B_\theta$  and  $B_s$ ) revealed that  $B_\theta$  dominated the B profile from the surface to  
458 800 m and  $B_s$  reduced the B in the 800 – 1000 m layer because of low salinity of LSW. Deeper,  $B_s$   
459 increased B due to the deep halocline (LSW-ISOW) that acted as a physical barrier limiting the depth  
460 of the convection.

461 During 2016 – 2018, the air-sea buoyancy losses were close to the climatological values and the very  
462 deep convection was possible thanks to the favorable preconditioning of the water column. It was  
463 surprising that these events reached convection depths similar to those observed in W2012 and  
464 W2015, when the latter were provoked by high air-sea buoyancy loss intensified by the effect of  
465 strong wind stress. It was also surprising that the water column remained favorably preconditioned  
466 during three consecutive winters without strong atmospheric forcing. In this paper, we studied the  
467 reasons why this happened.

468 The preconditioning for deep convection during 2016 – 2018 was particularly favorable due to the  
469 combination of two types of hydrographic anomalies affecting different depth ranges. First, the  
470 surface and intermediate waters (down to 800 m) were favorably preconditioned because buoyancy  
471 (density) decreased (increased) due to the cooling caused by the atmospheric forcing. Second,  
472 buoyancy (density) increased (decreased) in the layer 1,200 – 1,400 m due to the decrease in S  
473 caused by the lateral advection of fresher LSW formed in the Labrador Sea. The S anomaly of this  
474 layer resulted in a deeper deep halocline. Hence, the cooling of the intermediate water was essential  
475 to reach convection depth of 800 – 1,000 m, and the freshening in the layer 1,200 – 1,400 m and the  
476 associated deepening of the deep halocline, allowed the very deep convection (> 1,300 m) in W2016  
477 – W2018.

478 **Author contribution:** PZ treated and analyzed the data. PZ and HM interpreted the results. PZ, HM  
479 and VT discussed the results and wrote the paper.

480 **ACKNOWLEDGEMENT**

481 The Argo data were collected and made freely available by the International Argo Program and the  
482 national programs that contribute to  
483 it. (<http://www.argo.ucsd.edu>, <http://argo.jcommops.org>). The Argo Program is part of the Global  
484 Ocean Observing System. The NAO data were downloaded from the UCAR Climate Data Guide  
485 website (Schneider et al., 2013): [https://climatedataguide.ucar.edu/climate-data/hurrell-north-](https://climatedataguide.ucar.edu/climate-data/hurrell-north-atlantic-oscillation-nao-index-pc-based)

596

597 Table 1. Properties of the deep convection SECF and in the Labrador Sea in winters 2015 – 2018. We  
 598 show: the maximal MLD observed, the aggregate maximum depth of convection Q3, the  $\sigma_0$ , S and  $\theta$   
 599 of the winter mixed layer formed during the convection event and n, which is the number of Argo  
 600 profiles indicating deep convection. The uncertainties given with  $\sigma_0$ , S and  $\theta$  are the standard  
 601 deviation of the n values considered to estimate the mean values.

SECF	Maximal MLD (m)	Q3 MLD (m)	$\sigma_0$	Salinity	$\theta$	n
<b>W2015</b>			27.733 ± 0.007	34.866 ± 0.013	3.478 ± 0.130	29
	1710	1205				
<b>W2016</b>			27.746 ± 0.002	34.871 ± 0.003	3.388 ± 0.032	3
	1575	1471				
<b>W2017</b>			27.745 ± 0.007	34.868 ± 0.007	3.364 ± 0.109	3
	1400	1251				
<b>W2018</b>			27.748 ± 0.001	34.859 ± 0.003	3.263 ± 0.031	2
	1300	1300				
LABRADOR SEA	Maximal MLD	Q3 MLD	$\sigma_0$	Salinity	$\theta$	n
<b>W2015</b>	1675	1504	27.733 ± 0.009	34.842 ± 0.010	3.279 ± 0.036	41
<b>W2016</b>	1801	1620	27.743 ± 0.006	34.836 ± 0.010	3.124 ± 0.047	18
<b>W2017</b>	1780	1674	27.752 ± 0.008	34.853 ± 0.009	3.172 ± 0.029	26
<b>W2018</b>	2020	1866	27.756 ± 0.006	34.855 ± 0.010	3.145 ± 0.083	13

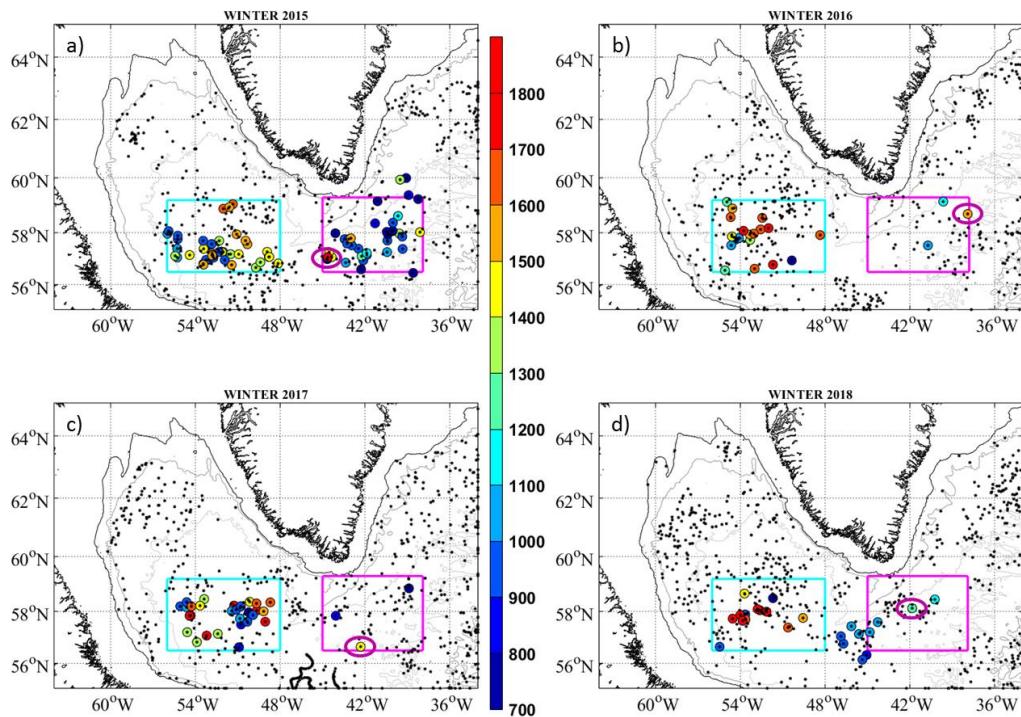

602

603

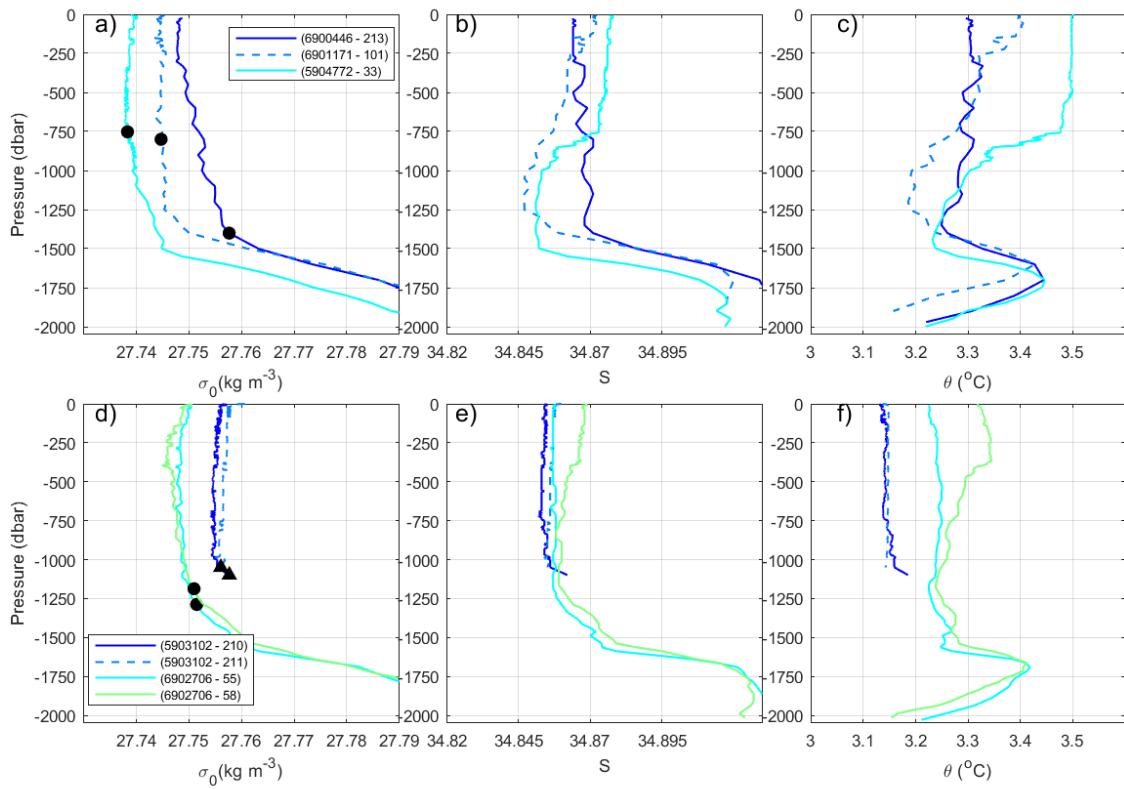

604

605

606

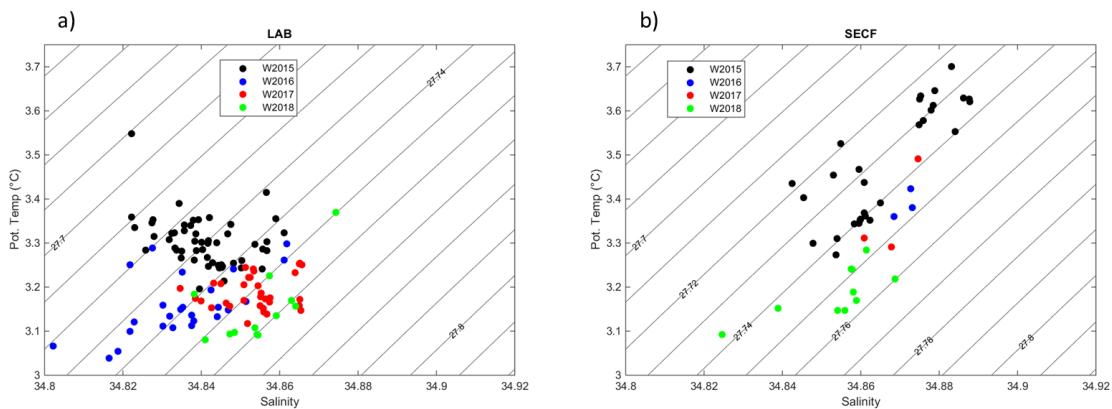

609 **Figure 1.** Positions of all Argo float north of 55°N in the Atlantic between 1 January and 30 April a)  
 610 2015, b) 2016, c) 2017 and d) 2018 (black and colored points). The colored points and color bar  
 611 indicate the mixed layer depth (MLD) when MLD was deeper than 700 m. The pink circles indicate  
 612 the position of the maximal MLD observed SECF each winter. The pink and cyan boxes delimit the  
 613 regions used for estimating the time series of atmospheric forcing and the vertical profiles of  
 614 buoyancy to be removed in the SECF region and the Labrador Sea, respectively (SECF: 56.5°N –  
 615 59.3°N and 45.0°W – 38.0°W, Labrador Sea: 56.5°N – 59.2°N and 56°W – 48°W).

616

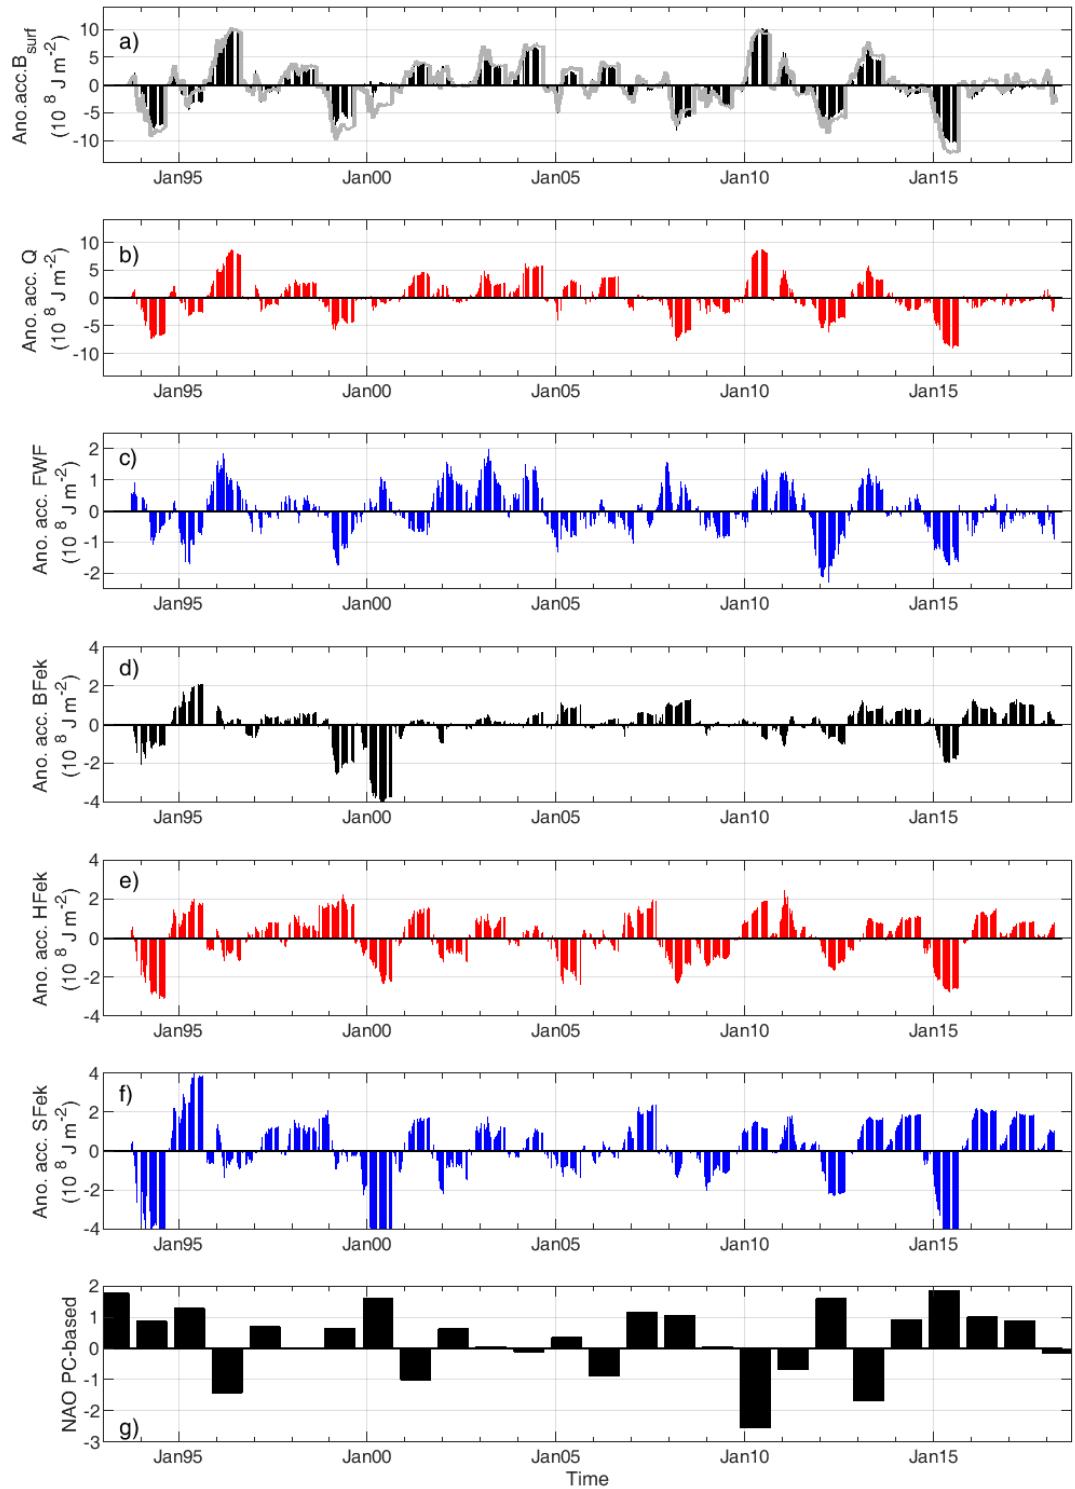

617 **Figure 2.** Vertical distribution of  $\sigma_0$ , S and  $\theta$  of Argo profiles showing MLD deeper than 700 m SECF in  
 618 Winter 2017 (a, b and c) and in Winter 2018 (d, e, f). The black points indicate the MLD. The triangles  
 619 in d) are the MLD which coincided with the maximal profiling pressure reached by the float. In the  
 620 legend, the float and cycle of each profile are indicated.

621

622 **Figure 3.** TS diagrams in the mixed layer for profiles with MLD deeper than 700 m during winters  
 623 2015, 2016, 2017 and 2018 for a) the Labrador Sea and b) SECF. The properties of the mixed layers  
 624 were estimated as the vertical means between 200 m and the MLD.

**SE CAPE FAREWELL**

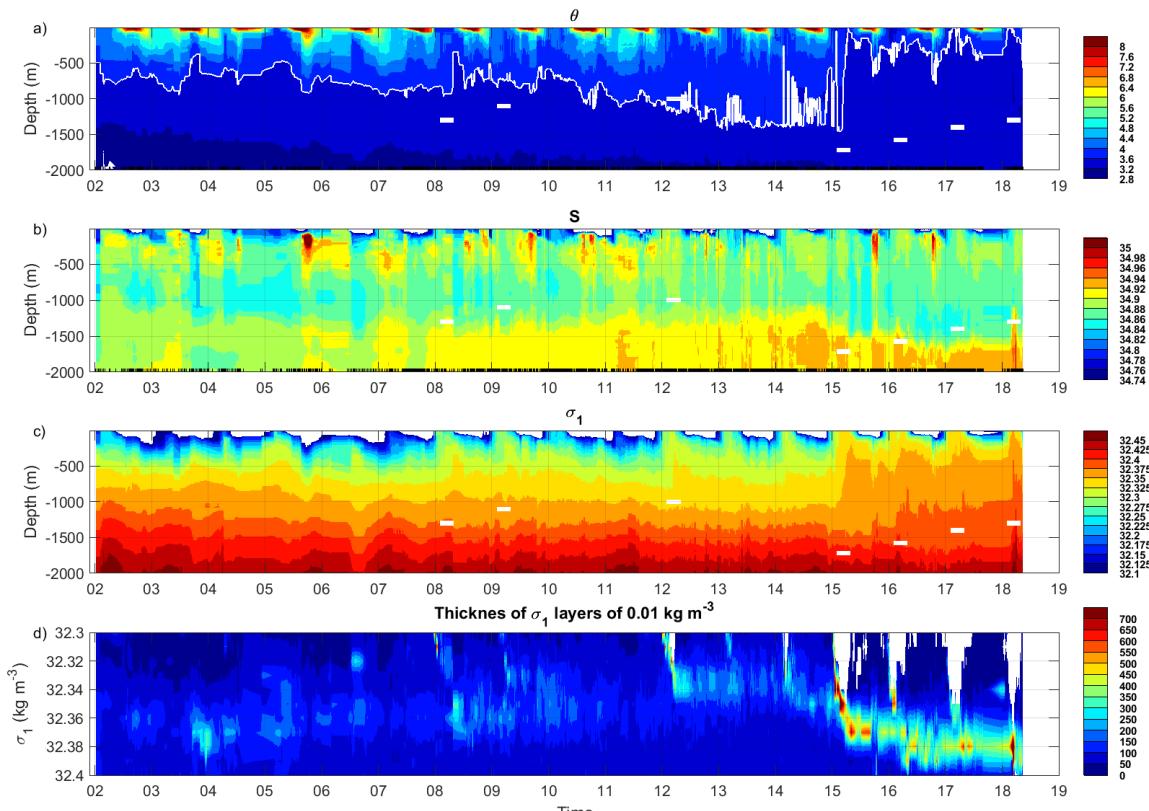

625  
626

**Figure 4.** Time series of anomalies of accumulated a) Bsurf\*, b) Q, c) FWF\*, d) BF<sub>ek</sub>, e) HF<sub>ek</sub> and f) SF<sub>ek</sub>,

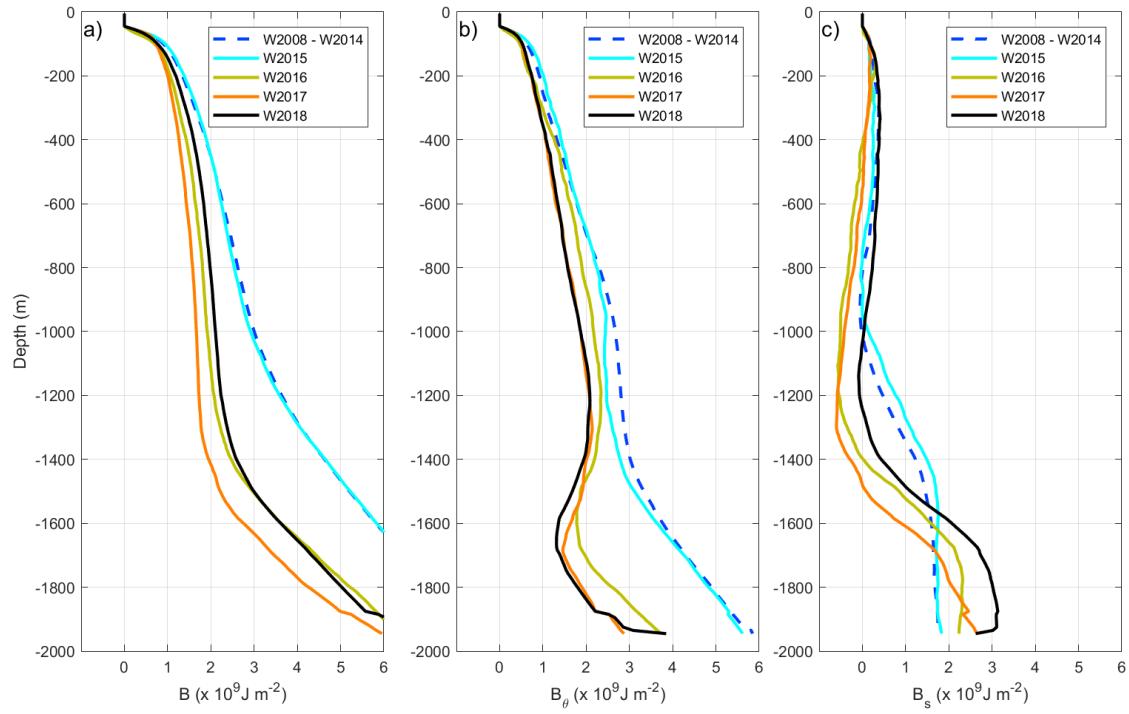

627 averaged in the SECF region. They are anomalies with respect to 1993 – 2016. The accumulation was  
 628 from 1 September to 31 August the following year. The winter NAO index (Hurrel et al., 2018) is also  
 629 represented in g). Gray line in a) is the sum of the anomalies of accumulated  $B_{\text{surf}}^*$  and  $BF_{\text{ek}}$ . Note that  
 630 the range of values in the y-axis is not the same in all the plots.

631

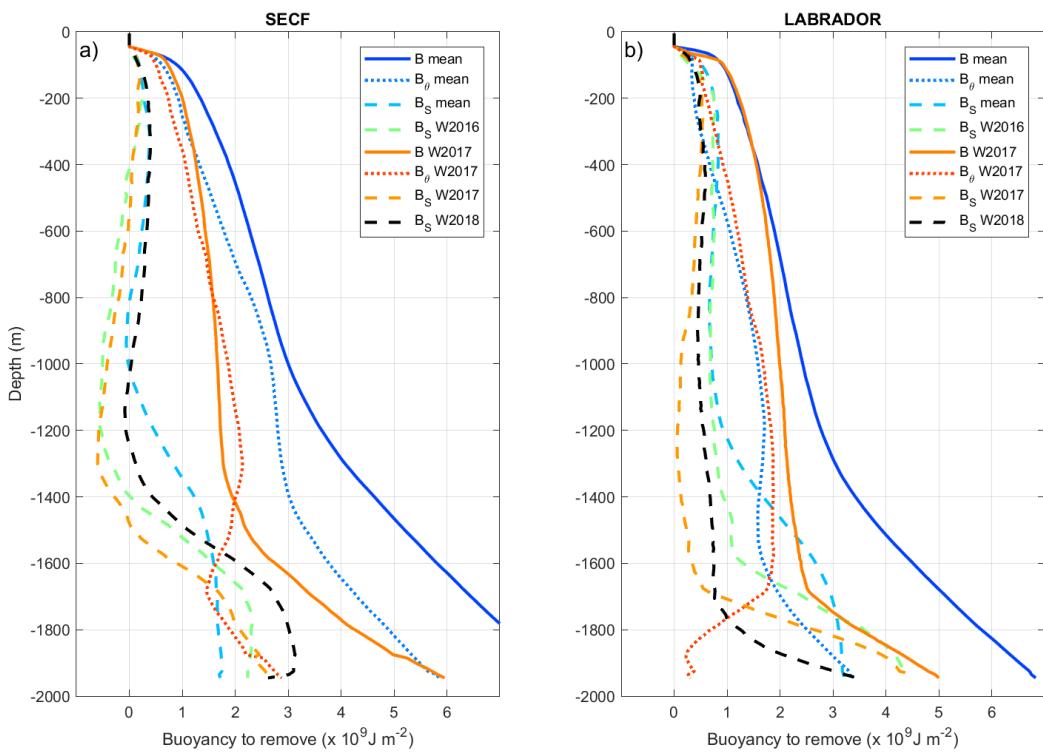

632  
 633 **Figure 5.** Time-evolutions of vertical profiles measured from Argo floats in the SECF region: a)  $\theta$ ; b)  $S$ ;  
 634 c)  $\sigma_1$  and d) thickness of  $0.01 \text{ kg m}^{-3}$  thick  $\sigma_1$  layers. The white horizontal bars in plots a), b) and c)  
 635 indicate the maximal convection depth observed in Irminger Sea or SECF when deep convection  
 636 occurred. The white line in plot a) indicates the depth of the isotherm  $3.6^\circ\text{C}$ . The black vertical ticks  
 637 on the x-axes of plot b) indicate times of Argo measurements. These figures were created from all  
 638 Argo profiles reaching deeper than 1000 m in the SECF region ( $56.5^\circ - 59.3^\circ\text{N}$ ,  $45^\circ - 38^\circ\text{W}$ , pink box in  
 639 Fig. 1). The yearly numbers of Argo profiles used in this figure are shown in Fig. S5.

640

641

642 **Figure 6.** Vertical profile of a) the buoyancy to be removed ( $B$ ), b) the thermal component ( $B_\theta$ ) and c)  
 643 the salinity component ( $B_s$ ). They were calculated from all Argo data measured in the SECF box (see  
 644 Fig. 1) in September before the winter indicated in the legend. For W2015 and W2018, we  
 645 considered data from 15/08/2017 to 30/09/2017 because not enough data were available in  
 646 September. The number of Argo profiles taken into account to estimate the  $B$  profiles was more than  
 647 ten for all the winters.

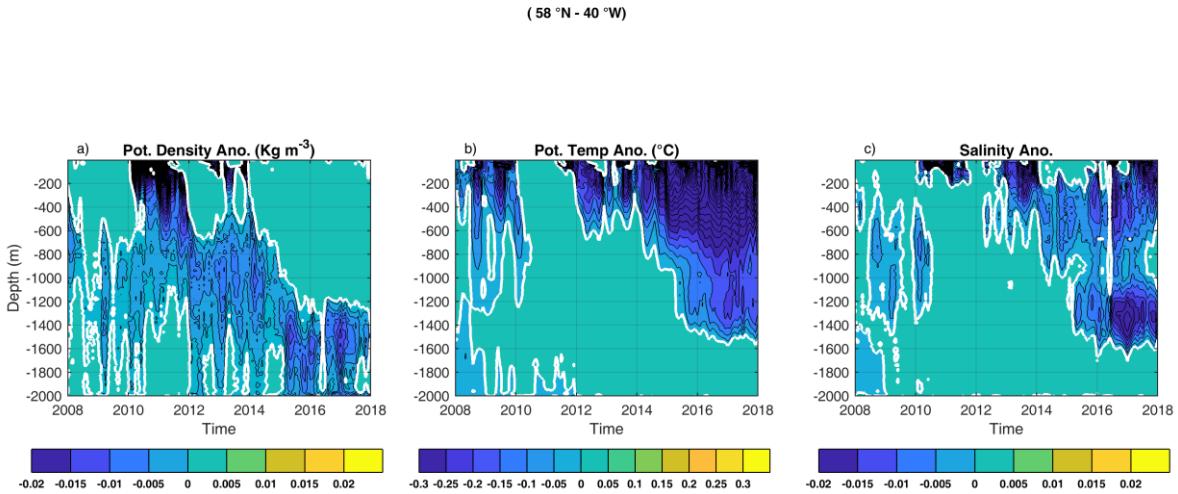

648

649 Figure 7. Decomposition of profiles of buoyancy to be removed (B, continuous lines) in its thermal  
 650 ( $B_\theta$ , dotted lines) and salinity ( $B_s$ , dashed lines) components in a) the SECF region; b) the Labrador  
 651 Sea. The  $B_s$  components for W2016 and W2018 were added to show the evolution of the depth of  
 652 the deep halocline.

653

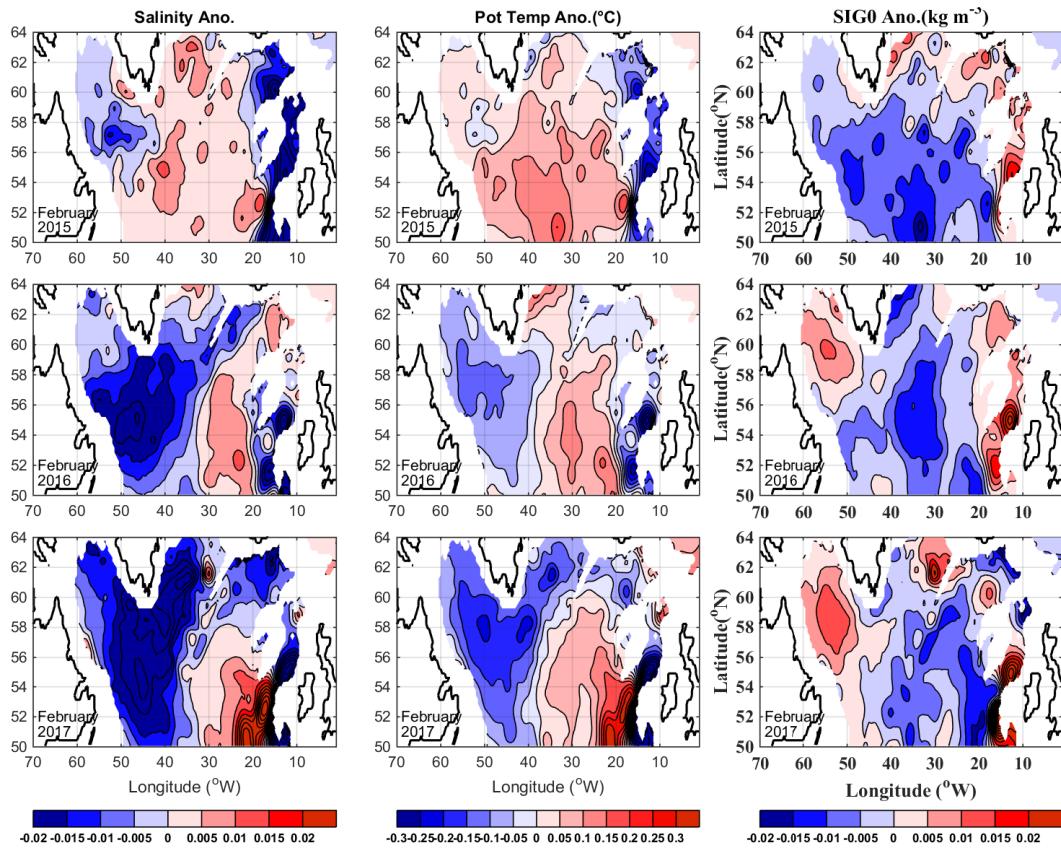

654

655

656

657 **Figure 8.** Evolution of vertical profiles of monthly anomalies of a)  $\sigma_0$ , b)  $\theta$  and c)  $S$ , at 58°N, 40°W. The  
658 anomalies were estimated from the ISAS database (Gaillard et al., 2016), and were referenced to the  
659 monthly mean estimated for 2002 – 2016.

660

661 **Figure 9.** Horizontal distribution of the anomalies of  $S$  (left panels),  $\theta$  (central panels) and  $\sigma_0$  (right  
662 panels) in the layer 1200 – 1400 m in February 2015 (upper panels), February 2016 (central panels)  
663 and February 2017 (lower panels). The monthly anomalies were estimated from ISAS database and  
664 are referenced to the period 2002 – 2016.
