9 **Abstract.**

10 Two feature-based verification methods, thus far only used for the diagnostic evaluation of atmospheric
11 models, have been applied to compare ~7 km resolution pre-operational analyses of Chlorophyll-*a* (Chl-
12 *a*) concentrations to a 1 km gridded satellite-derived Chl-*a* concentrations product. The aim of this
13 study was to assess the value of applying such methods to ocean models. Chl-*a* bloom objects were
14 identified in both datasets for the 2019 bloom season (March 1 to 31 July). These bloom objects were
15 analysed as discrete (2D) spatial features, but also as space-time (3D) features, providing the means of
16 defining the onset, duration, and demise of distinct bloom episodes and the season as a whole.

17 The new feature-based verification methods help reveal that the model analyses are not able to represent
18 small coastal bloom objects, given the coarser definition of the coastline. ~~The analyses~~ also wrongly
19 producinge more bloom objects in deeper Atlantic waters. Model analyses cConcentrations ~~in the model~~
20 ~~analyses~~ are somewhat higher overall. The bias manifests itself in the size of the model analysis bloom
21 objects, which tend to be larger than the satellite-derived bloom objects. ~~Based on these feature-based~~
22 ~~methods~~ The onset of the bloom season is delayed by 26 days in the model analyses, but the season
23 also persists for another month beyond the diagnosed end. The season was diagnosed to be 119 days
24 long in the model analyses, compared to 117 days from the satellite product. Geographically the model
25 analyses and satellite-derived bloom objects do not necessarily exist in a specific location at the same
26 time, and only overlap occasionally.

27 **1 Introduction**

28 The advancements in atmospheric numerical weather prediction (NWP) such as the improvements in
29 model resolution began to expose the relative weaknesses in so-called traditional verification scores
30 (such as the root-mean-squared-error for example), which rely on the precise matching in space and
31 time of the forecast to a suitable observation. These metrics and measures no longer provided adequate
32 information to quantify forecast performance (e.g. Mass et al. 2002). One key characteristic of high-
33 resolution forecasts is the apparent detail they provide, but this detail may not be in the right place at the
34 right time, a phenomenon referred to as the “double penalty effect” (Rossa et al., 2008). Essentially it
35 means that at any given time the error is counted twice because the forecast occurred where it was not
36 observed, and it did not occur where it was observed. This realisation created the need within the
37 atmospheric community for creating more informative yet robust verification methods. As a result, a
38 multitude of so-called “spatial” verification methods were developed, which essentially provide a
39 number of ways for accounting for the characteristics of high-resolution forecasts.

40

41 In 2007 a spatial verification method inter-comparison (Gilleland et al., 2009, 2010) was established
42 with the aim of providing a better collective understanding of what each of the new methods was
43 designed for, and categorising what type of forecast errors each could quantify. A decade later
44 Dorninger et al. (2018) revisited this inter-comparison, adding a fifth category so that all spatial
45 methods fall into one of the following groupings: neighbourhood, scale separation, feature-based,
46 distance metrics or field deformation.

47

48 The use of spatial verification methods has therefore become commonplace for atmospheric NWP (see
49 Dorninger et al. (2018) and references within). Neighbourhood-based methods in particular have
50 become popular due to the relative ease of computation and intuitive interpretation. Recently one such
51 neighbourhood spatial method was demonstrated as an effective approach for exploring the benefit of
52 higher resolution ocean forecasts (Crocker et al., 2020). Another class of methods focus on how well
53 particular features of interest are being forecast. Forecasting specific features of interest is one of the
54 main reasons for increasing horizontal resolution. Feature-based verification methods, such as the

55 Method for Object-based Diagnostic Evaluation (MODE, Davis et al., 2006) and the time domain
56 version MODE-TD (Clark et al., 2014) enable an assessment of such features, focusing on the physical
57 attributes of the features (identified using a threshold) and how they behave at a given point in time, and
58 evolve over time. These methods require a gridded truth to compare to. Whilst the initial inter-
59 comparison project was based on analysing precipitation forecasts, over recent years their use has
60 extended to other variables, provided gridded data sets exist that can be used to compare against (e.g.
61 Crocker & Mittermaier (2013) considered cloud masks and Mittermaier et al., (2016) considered more
62 continuous fields in a global NWP model such as upper-level jet cores, surface lows and high pressure
63 cells using model analyses). Mittermaier & Bullock (2013) detailed the first study to use MODE-TD
64 prototype tools to analyse the evolution of cloud breaks over the UK using satellite-derived cloud
65 analyses.

66

67 In the ocean, several processes have strong visual signatures that can be detected by satellite sensors.
68 For example, mesoscale eddies can be detected from sea surface temperature or sea level anomaly (e.g.
69 (Chelton et al., 2011, Morrow and Le Traon, 2012, Hausmann and Czaja, 2012). Phytoplankton blooms
70 are seasonal events which see rapid phytoplankton growth as a result of changing ocean mixing,
71 temperature and light conditions (Sverdrup, 1953, Winder and Cloern, 2010, Chiswell, 2011)). Blooms
72 represent an important contribution to the oceanic primary production, a key process for the oceanic
73 carbon cycle (Falkowski et al., 1998). Their spatial extent and intensity in the upper ocean make them
74 visible from space with ocean colour sensors (Gordon et al., 1983, Behrenfeld et al., 2005).
75 Biogeochemical models coupled to physical models of the ocean provide simulations for the various
76 parameters that characterize the evolution of a spring bloom, such as Chl-*a* concentration which can
77 also be estimated from spaceborne ocean colour sensors (Antoine et al., 1996).

78

79 Validation of marine biogeochemical models has traditionally relied on simple statistical comparisons
80 with observation products, often limited to visual inspections (Stow et al., 2009; Hipsey et al., 2020). In
81 response to this, various papers have outlined and advocated using a hierarchy of statistical techniques
82 (Allen et al., 2007a, 2007b; Stow et al., 2009; Hipsey et al., 2020), multivariate approaches (Allen and

83 Somerfield, 2009), and novel diagrams (Jolliff et al., 2009). Many of these rely on matching to
84 observations in space and time, but some studies have started applying feature-based verification
85 methods (Mattern, et al.2010). Emergent properties have been assessed in terms of geographical
86 provinces (Vichi et al., 2011), phenological indices (Anugerahanti et al., 2018), and ecosystem
87 functions (de Mora et al., 2016). In a previous application of spatial verification methods developed for
88 NWP, Saux Picart et al. (2012) used a wavelet-based method to compare Chl-*a* concentrations from a
89 model of the European North West Shelf to an ocean colour product.

90

91 For this paper, both MODE and MODE-TD (or MTD for short) were applied to the latest pre-
92 operational analysis (at the time) of the Met Office Atlantic Margin Model (AMM7) at 7 km resolution
93 (O’Dea et al., 2012; Edwards et al., 2012; O’Dea et al., 2017; King et al., 2018; McEwan et al., 2021)
94 for the European North West Shelf (NWS), in order to evaluate the spatio-temporal evolution of the
95 bloom season in both model and observation fields. ~~A full traditional verification of the system (e.g.,
96 using root mean squared error and similar metrics) is out of scope of this study and will be presented in
97 a separate publication.~~ For comparison with the MODE and MTD results, a few traditional metrics are
98 included here, based on the Copernicus Marine Environment Monitoring Service (CMEMS) Quality
99 Information Document for the model (McEwan et al., 2021). Traditional verification of a previous
100 version, prior to the introduction of ocean colour data assimilation, was presented by Edwards et al.
101 (2012), who used various metrics and Taylor diagrams (Taylor, 2001) to compare model analyses to
102 satellite and in-situ observations. Ford et al. (2017) presented further validation, to understand the skill
103 of the model at representing phytoplankton community structure in the North Sea. A similar version of
104 the system used in this study, including ocean colour data assimilation, was assessed in Skákala et al.
105 (2018), who validated both analysis and forecast skill using traditional methods. The assimilation
106 improved analysis and forecast skill compared with the free-running model, but when assessed against
107 satellite ocean colour the forecasts were not found to beat persistence. On the NWS the spring bloom
108 usually begins between February and April, varying across the domain and interannually (Siegel et al.,
109 2002; Smyth et al., 2014), and lasts until summer. Without data assimilation the spring bloom in the
110 model typically occurs later than in observations (Skákala et al., 2018, 2020), a bias which is largely

111 corrected by assimilating ocean colour data. The purpose of this study using feature-based methods is to
112 further explore and quantify the benefit and impact of the data assimilation on the evolution of modelled
113 Chl-*a* concentrations. In Section 2 the data sets used in the verification process are introduced. Section 3
114 describes MODE and MTD. Section 4 contains a selection of results, and their interpretation.
115 Conclusions and recommendations follow in Section 5.

116 **2 Data sets for the 2019 Chl-*a* bloom**

117 As stated in Section 1, feature-based methods such as MODE and MTD require the fields to be
118 compared to be on the same grid. The model grid is the coarser grid and is used here, with the satellite-
119 derived gridded ocean colour products interpolated to the model grid. -

120 **2.1 Satellite-derived gridded ocean colour products**

121 A cloud-free gridded (space-time interpolated, L4) daily product delivered through the Copernicus
122 Marine Environment Monitoring Service (CMEMS, Le Traon et al., 2019) catalogue provides Chl-*a*
123 concentration at ~1 km resolution over the Atlantic (46°W–13°E, 20°N–66°N). The L4 Chl-*a* product is
124 derived from merging of data from multiple satellite-borne sensors: MODIS-Aqua, VIIRS-N and OLCI-
125 S3A. The reprocessed (REP) products available nearly 6 months after the measurements
126 (OCEANCOLOUR_ATL_CHL_L4_REP_OBSERVATIONS_009_098) are used here as it is the best-
127 quality gridded product available for comparison. The satellite derived Chl-*a* concentration estimate is
128 an integrated value over optical depth.

129

130 Errors in satellite-derived Chl-*a* can be more than 100% of the observed value (e.g. Moore et al., 2009).
131 The errors in the L4 Chl-*a* values are often at their largest near the coast, especially near river outflows.
132 However, in the rest of the domain, smaller values of Chl-*a* mean that even large percentage
133 observation errors result in errors typically smaller than the difference between model and observations.
134 As will be shown, the models at 7 km resolution cannot resolve the coasts in the same way as is seen in
135 the satellite product as some of the coastal Chl-*a* dynamics are sub-grid scale for a 7 km resolution
136 model.

137

138 For this study the ~1 km resolution L4 satellite product was interpolated onto the AMM7 grid using
139 standard two-dimensional horizontal cubic interpolation. This coarsening process retained some of the
140 larger concentrations present in the L4 product.

141 **2.2 Model description**

142 Operational modelling of the NWS is performed using the Forecast Ocean Assimilation Model (FOAM)
143 system. This consists of the NEMO (Nucleus for European Modelling of the Ocean) hydrodynamic
144 model (Madec et al., 2016; O'Dea et al., 2017), the NEMOVAR data assimilation scheme (Waters et al.,
145 2015; King et al., 2018), and for the NWS region the European Regional Seas Ecosystem Model
146 (ERSEM), which provides forecasts for the lower trophic levels of the marine food web (Butenschön et
147 al., 2016). The version of FOAM used in this study is AMM7v11, using the ~7 km horizontal
148 resolution domain stretching from 40 °N, 20 °W to 65 °N, 13 °E. Operational forecasts of ocean physics
149 and biogeochemistry for the NWS are delivered through CMEMS, for a summary of the principles
150 underlying the service see e.g. Le Traon et al. (2019).

151

152 AMM7v11 uses the CO6 configuration of NEMO, which is configured for the shallow water of the
153 shelf sea and is a development of the CO5 configuration described by O'Dea et al. (2017). The ERSEM
154 version used is v19.04, coupled to NEMO using the Framework for Aquatic Biogeochemical Models
155 (FABM, Bruggeman and Bolding, 2014). The NEMOVAR version is v6.0, with a 3D-Var method used
156 to assimilate satellite and in situ sea surface temperature (SST) observations, in situ temperature and
157 salinity profiles, and altimetry data into NEMO (King et al., 2018), and chlorophyll derived from
158 satellite ocean colour into ERSEM (Skákala et al., 2018). The introduction of ocean colour assimilation
159 in AMM7v11 is a major development for the biogeochemistry over previous versions of the system
160 (Edwards et al., 2012). The satellite ocean colour observations assimilated are from a daily L3 multi-
161 sensor composite product based on MODIS and VIIRS with resolutions of 1 km for the Atlantic (for
162 further information see OCEANCOLOUR_ATL_CHL_L3_NRT_OBSERVATIONS_009_036 on the

163 CMEMS catalogue). The L3 product is based on two of the same three ocean colours sensors used in
164 the L4 product described in Section 2.1, but with different processing and no gap-filling.

165

166 In this study daily mean Chl-*a* concentrations for the period of 1 March-31 July 2019 from AMM7v11
167 were used to illustrate the verification methodology. AMM7v11 entered operational use in December
168 2020, and the data used here came from a pre-operational run of the system. Note only the analysis of
169 AMM7v11 (i.e. no corresponding forecasts) was available at the time of the assessment, and the results
170 presented in this paper show how close the data assimilation draws the model to the observed state.

171 **2.3 Visual inspection of data sets**

172 Ideally, Chl-*a* concentration from the model should be integrated over optical depth to be equivalent to
173 the satellite derived value defined in Section 2.1 (Dutkiewicz et al., 2018). However, this is currently a
174 non-trivial exercise, and cannot be accurately calculated from offline outputs. Therefore, the commonly
175 accepted practice is to use the model surface Chl-*a* (Lorenzen, 1970, (Shutler et al., 2011)). Here it is
176 assumed that the difference between surface and optical depth-integrated Chl-*a* is likely to be small in
177 comparison with the actual model errors.

178

179 **Figure 1 (a) Daily mean L4 multi-sensor observations regrided on the 7 km resolution model grid and (b) AMM7v11**
 180 **Chl-*a* for 1 June 2019. (c) Error estimates on the multi-sensor L4 Chl-*a* and (d) difference between AMM7v11 and**
 181 **the L4 product.**

182

183 Figure 1 shows the L4 ocean colour product (a) and AMM7v11 analysis (b) for 1 June 2019 on
 184 the top row, using the same plotting ranges. The second row shows the difference field that is provided
 185 with the L4 ocean colour product (c), and the AMM7v11 minus L4 difference field (d). The mean error
 186 (bias) is generally positive with the AMM7v11 analysis containing higher Chl-*a* concentrations,
 187 especially in the deeper North Atlantic waters. The exceptions are along the coast where the AMM7v11
 188 analysis is deficient, but it should be noted that these are also the zones where some of the largest
 189 satellite retrieval errors occur and where a 7-km resolution model, with a coarse representation of the
 190 coast, does not fully represent complex coastal and estuarine processes.

191 **3 Method for Object-based Diagnostic Evaluation (MODE) and MODE Time-Domain (MTD)**

192 **3.1. Description of the methods**

193 This section provides a brief description of the Method for Object-Based Diagnostic Evaluation
194 (MODE), first described in Davis et al. (2006) and its extension MODE Time-Domain (MTD).
195

196 MODE and MTD can be used on any temporal sequence of two gridded data sets which contain features
197 that are of interest to a user (whoever that user may be, model developer or more applied). By extracting
198 only the feature(s) of interest, the method allows one to mimic what humans do, but in an objective
199 way. Once identified the features can then be mathematically analysed over many days or seasons to
200 compute aggregate statistics of behaviour. MODE can be used in a very generalised way. The key
201 requirements are to 1) have gridded fields to compare and 2) be able to set a threshold for identifying
202 features of interest.

203

204 In this instance the comparison will involve the AMM7v11 model data assimilation analysis and the
205 gridded L4 satellite product. MODE identifies the features (called objects), as areas for which a
206 specified threshold is exceeded, here it is a Chl-*a* concentration. Consider ~~Figure 2~~ [Figure 2](#) which
207 shows a number of objects that have been identified after a threshold has been applied to two fields
208 (blue and orange). The identified objects in the two fields are of different sizes and shapes and do not
209 overlap in space, though they are not far apart. Object characteristics or attributes such as the area and
210 mass-weighted centroid are computed for each single object. Simple (also known as single) objects can
211 be *merged* (to form clusters) within *one* field (illustrated here for the orange field). This may be useful
212 to do if it is clear that there are many small objects close together which should really be treated as one.
213 Furthermore, objects in one field can be *matched* to objects in the other field. To find the best match an
214 interest score is computed for each possible pairing between all identified objects. The components used
215 for computing the interest score can be tuned to meet specific user needs. In ~~Figure 2~~ [Figure 2](#)(a) it is
216 based on the area ratio, intersection-area ratio, minimum boundary distance and centroid difference.
217 Furthermore, the components can be weighted according to relative importance. Given a scenario where
218 there are 2 identified objects in the blue field and 3 in the orange field ~~Figure 2~~ [Figure 2](#)(b) shows the

219 interest score for each possible pairing in this hypothetical example. Only the pairing with the highest
 220 score is analysed further, and only if it exceeds the set threshold for defining an acceptable match. The
 221 default value for this is 0.7. ~~In For~~ the example in Fig. 2(b), blue object 1 is best matched against orange
 222 object 1, and this match is used in the analysis. Note that there is another good match with orange object
 223 2 as it is above the threshold of 0.7, but it, as well as the orange object 3 would not be used, with orange
 224 object 3 below the 0.7 threshold. In all likelihood a scenario such as shown in Figure 2~~Figure 2~~(b)
 225 would be assessed as clusters with blue objects 1 and 2 forming a cluster and orange objects 1 and 2
 226 also forming a cluster. An interest score for the cluster pairing above 0.7 would then create a matched
 227 pair. Once these matches are completed summary statistics describing the individual objects (both
 228 matched and unmatched) and matched object pairs are produced. These statistics can be used to identify
 229 similarities and differences between the objects identified in two different data sets, which can provide
 230 diagnostic insights on the relative strengths and weaknesses of one compared to the other.

231
 232 **Figure 2 Schematic illustrating some of the key components of identifying objects using MODE. (a) Defining some of**
 233 **the terminology and key components for computing matched pairs. (b) Example of how the best matched pair is**
 234 **identified.**

235

236 The important steps for applying MODE can be summarised as follows (which are described in detail in
237 Davis et al. 2006):

- 238 1) Both forecast and observation (or analysis) need to be on the same grid. Typically, this means
239 interpolating the observations to the model grid to avoid the model being expected to resolve
240 features which are sub-grid scale.
- 241 2) Depending on how noisy the fields are they should be smoothed. Gridded observations (not
242 analyses) can be noisy and usually need some smoothing. Models and model analyses are built
243 on numerical methods which come with discretisation effects. Depending on the method this
244 implies that any model's true resolution (i.e. the scales which the model is resolving) is between
245 2 and 4 times the horizontal grid (mesh) resolution. The number of objects identified will vary
246 inversely with the smoothing radius.
- 247 3) Define a threshold which captures the feature of interest and apply it to both the smoothed
248 forecast and observed fields to identify simple objects as shown in [Figure 2](#)~~Figure 2~~.
- 249 4) Any smoothing is only for object identification purposes. The original intensity information
250 within the object boundaries is analysed.
- 251 5) Lastly, the object matching is accomplished using a fuzzy logic engine (low level artificial
252 intelligence), which is expressed as the so-called "interest" score as shown in [Figure 2](#)~~Figure~~
253 [2](#)(b). The higher the score the stronger the match. All objects are compared in both fields and
254 interest scores are computed for all combinations. A threshold is set on the interest score value
255 (typically 0.7) to denote which are the best matches, and on the unique pairing with the highest
256 score is kept for analysis purposes. Some objects will remain unmatched (either because there is
257 none or because there are no interest values above the set threshold to provide a credible match)
258 and these can be analysed separately.

259 MODE is highly configurable. To gain an optimal combination of configurable parameters for each
260 application requires extensive sensitivity testing to gain sufficient understanding of the behaviour of the
261 data sets to be examined, and to achieve, on average, heuristically the right outcome. Initial tuning
262 requires user input to check whether the method is replicating what a human would do.

- 263 1) The sensitivity to threshold and smoothing radius should be explored. The threshold and
264 variability in the fields can affect the number of objects which are identified. The process of
265 exploring the relationship between threshold and smoothness helps to identify what would
266 heuristically be considered a reasonable number of objects.
- 267 2) The sensitivity to the merging option must also be investigated. In this instance the merging
268 option had very little impact.
- 269 3) The behaviour of the matching can also be configured, with a number of options ranging from
270 the simple to the more complicated, which added computational expense. There may be very
271 little difference in outcomes, but it is worth checking. Here the *merge_both* option was used but
272 it was not strictly necessary as there was little difference between the available options.

273

274 Note also that a minimum size (area) is set for object identification. This is often a somewhat pragmatic
275 choice. If the size is set too small, too many objects are identified, which end up being merged. If too
276 large, very few objects are identified. Here a minimum area of 10 grid squares ($\sim 70 \text{ km}^2$) was used for
277 an object to be included in the analysis. For this study the default settings were used for matching and
278 computing the interest score (as provided in the default configuration file (see example configuration
279 files in https://github.com/dtcenter/MET/tree/main_v8.1/met/scripts/config). The default threshold of
280 0.7 for the interest score was also used to identify acceptable matches.

281

282 Identical to MODE, identifying time-space objects in MTD uses smoothing and thresholding. Applying
283 a threshold yields a binary field where grid points exceeding the defined threshold are set to one. At this
284 stage each region of non-zero grid points in space and time is considered a separate object, and the grid
285 points within each object are assigned a unique object identifier. For MTD the search for contiguous
286 grid points not only means examining adjacent grid points in space, but also the grid points in the same
287 or similar location at adjacent times to define a space-time object. The same fuzzy logic-based
288 algorithms used for merging and matching in MODE apply to MTD as well. Similarly, to MODE a
289 minimum volume must be set. Here a volume threshold of 1000 grid squares (a summation of the daily
290 object areas identified to be part of the space-time object) was imposed for space-time object

291 identification to be included in the analysis. This represents the accumulated number of grid squares
292 associated with an object over consecutive time slices. Otherwise, the default settings were used for
293 object matching. For MTD a lower interest score of 0.5 was used for matching objects. Finally, it is
294 worth noting that the MODE and MTD tools, though similar, are completely independent of each other,
295 and were set up differently here. MODE is ideal for understanding the identified features in individual
296 daily fields in some detail. MTD, it was felt, would be best used to look at larger scales. Here it was set
297 up to capture the most significant (in size) and long-lasting blooms.

298

299 **3.2 Defining Chl-*a* concentration thresholds and other choices on tuneable parameters**

300 Chl-*a* can vary over several orders of magnitude. Often \log_{10} thresholds are used to match the fact that
301 Chl-*a* follows a lognormal distribution (e.g., Campbell, 1995). Defining thresholds can be difficult: on
302 the one hand there is the desire to only capture events of interest, so the thresholds should not be too
303 low, whereas on the other hand if the thresholds are too high no events are captured and there is nothing
304 to analyse. From a regional (NW European Shelf) perspective the values of interest are typically in the
305 range of 3–5 mg m^{-3} (Schalles, 2006), though higher Chl-*a* concentrations can be measured *in-situ* or
306 diagnosed in satellite products. For this study, the data sets were not log-transformed but ~~the~~ thresholds
307 were selected in such a way that they would correspond to being equally spaced in logarithmic space
308 (where the Chl-*a* concentrations are approximately Gaussian), staying better reflecting the skewed true
309 ~~to the~~ underlying distribution shape of Chl-*a* concentrations. Three thresholds analysed: 2.5, 4 and 6.3
310 mg m^{-3} . Here the primary focus is on the results for the 2.5 mg m^{-3} threshold, though some results for
311 the 4 and 6.3 mg m^{-3} thresholds are also presented.

312

313 In addition to the interpolation of the L4 ocean colour product onto the ~7 km AMM7v11 grid, it is
314 important to ensure that MODE and MTD use optimal settings for the fields under study. Results are
315 sensitive to characteristics of the fields (how smooth or noisy). Right at the start the emphasis was on
316 finding the right combination of Chl-*a* concentration threshold and smoothing, balancing the need for
317 identifying objects with keeping the number of objects manageable. The guiding principles in
318 identifying the right combination were to ensure that the daily object count remained low enough,

319 recalling that these methods were developed to mimic what a human would do. The human brain would
320 struggle to cope with as many as 30, but this was considered to be an acceptable upper limit after
321 considerable visual inspection of output. Furthermore, the smoothing applied needs to be reduced with
322 increasing concentration thresholds because objects become smaller and are less frequent. This is to
323 ensure that too much smoothing does not remove more intense objects from the analysis. However,
324 pushing the concentration threshold too high may also be detrimental; depending on the input fields,
325 identified objects may be spurious (due to, for example, e.g., a failure of quality control processes
326 removing such). Too few objects also make the compilation of robust aggregated statistics impossible.

327

328 For the lower~~est~~ thresholds, ~~including~~ 2.5 and 4.0 mg m⁻³, a smoothing radius of 5 grid squares (~35 km)
329 was applied to both L4 and AMM7v11 fields, but for high~~est~~ thresholds (~~heree-g.~~ 6.3 mg m⁻³) the
330 smoothing radius was reduced to 3 grid squares, to prevent the higher peak concentrations, which are
331 often small in spatial extent, from being lost due to the smoothing. Tests of thresholds above 6.3 mg m⁻³
332 yielded too few objects to be analysed with any rigour. The smoothing was particularly necessary for
333 the L4 product which, because of its native 1 km resolution is able to resolve very small (noisy) objects
334 typically found near the coast and which a 7 km resolution model cannot resolve. For the MTD
335 analysis, objects in the L4 ocean colour product and the AMM7v11 analyses were only defined using a
336 Chl-*a* concentration threshold of 2.5 mg m⁻³.

337

338 4. Results

339 4.1 Traditional statistics

340 Traditional verification metrics are based on a set of observations and a set of model outputs matched in
341 time and space. The statistics that are typically considered (McEwan et al., 2021) are the median error
342 (bias), median absolute difference (MAD) and Spearman rank correlation coefficient. The median bias
343 gives indication of consistent differences between the model and observations, with a positive bias
344 indicating the model concentration is higher than observed. The MAD provides an absolute magnitude
345 of the difference. The Spearman rank correlation coefficient is the Pearson correlation coefficient
346 between the ranked values of the model and observation data so that if the model data increases when
347 the observations do, they are positively correlated. It has the same interpretation as the more common
348 Pearson correlation coefficient where a correlation of 1 shows perfect correlation and 0 shows no
349 correlation. [Figure 3](#) provides a map of the model domain and the subregions over which
350 traditional metrics are computed. Table 1 shows results for log(Chl-*a*) assessed against the L4 ocean
351 colour product.

Regions:

EC: English Channel

IS: Irish Sea

NNS: Northern North Sea

NT: Norwegian Trench

NWA: North Western Approaches

SNS: Southern North Sea

SWA: South Western Approaches

The Continental Shelf regions includes all the above, i.e. all regions except Off-shelf.

Observation stations:

L4: station L4 of the Western Channel Observatory

352

372

373 **Table 1 Statistics for matched-pairs of for** daily model surface log-chlorophyll-*a* outputs and satellite ocean colour
 374 **Chl-*a* for the full domain and sub-regions for the period March to July 2019. See Figure 3** for the location of
 375 **the regions. The Continental shelf includes all regions except Off-shelf (ICES, 2014)**

<i>Region</i>	<i>Median bias (log(mg m⁻³))</i>	<i>MAD (log(mg m⁻³))</i>	<i>Spearman correlation coefficient</i>
Full Domain	<0.01 (0.004)	0.21	0.62
Continental shelf	-0.09	0.17	0.71
Off-shelf	0.06	0.23	0.51
Norwegian Trench	-0.04	0.18	0.61
Northern North Sea	-0.05	0.17	0.64
Southern North Sea	-0.17	0.19	0.82
English Channel	-0.13	0.16	0.68
Irish Sea	-0.13	0.19	0.49
South Western Approaches	-0.07	0.15	0.69
North Western Approaches	<0.01 (0.006)	0.18	0.51

376

377 Compared with the L4 product, the AMM7v11 analysis slightly overestimates Chl-*a* off-shelf, and
 378 underestimates Chl-*a* in the on-shelf regions (Table 1). Regions show moderate to strong
 379 positive correlations, highest in the Southern North Sea and lowest in the Irish Sea. These statistics give
 380 useful insight into model skill but provide limited information about how model performance changes
 381 as the bloom season progresses (McEwan et al., 2021; Skákala et al., 2018, 2020). As will be shown, the
 382 output from MODE and MTD provides a very different perspective from these traditional verification
 383 metrics, allowing a more detailed understanding of model performance.

384

385 4.2 Chl-*a* distributions

386 It is important to understand the nature of the underlying L4 and AMM7v11 Chl-*a* distributions and any
 387 differences between them. This can be done by creating cumulative distribution functions (CDF) of the
 388 log₁₀ L4 and AMM7v11 Chl-*a* concentrations, by taking all grid points in the domain and all dates in
 389 the study period. These are plotted in Figure 4, showing that there is an offset between the

390 distributions, the AMM7v11 analysis having more low concentrations, though the distributions appear
391 to be converging in the upper tail.

392

393 **Figure 4 Empirical cumulative distribution functions of the log₁₀ Chl-*a* concentration for the L4 ocean colour**
394 **product and AMM7v11 analyses for the 2019 bloom season.**

395 Exploring this further the AMM7v11 and L4 Chl-*a* concentration CDFs can be derived for each
396 individual day, rather than for the season as a whole. From these the quantile where the L4 product is
397 less than or equal to 2.5 mg m⁻³ (29.7%) can be compared to the corresponding AMM7v11
398 concentration associated with the same quantile of 29.7%. From ~~Figure 4~~Figure-4 this gives an
399 equivalent concentration of 1.15 mg m⁻³ for the season. The daily matched quantile Chl-*a* values
400 provide an estimate of the daily bias. This is plotted in ~~Figure 5~~Figure-5 as a time series for the 2019
401 bloom season. It shows that the daily AMM7v11 corresponding quantile values are mainly in the range
402 of ~1.5—4.5 mg m⁻³, averaging out to 2.9 mg m⁻³ over the season, which suggests a modest difference
403 overall. The larger day-to-day variations show some cyclical patterns. There are notable peaks at the
404 end of May and the beginning of July. An inspection of the fields (not shown) suggests that at these

405 times the AMM7v11 appears to have higher Chl-*a* concentrations over large portions of the domain
406 compared to the L4 product.

407
408 **Figure 5** The day-to-day AMM7v11 quantile Chl-*a* value corresponding to the L4 product quantile representing 2.5
409 **mg m⁻³** derived from the L4 daily CDFs. The mean AMM7v11 Chl-*a* equivalent quantile value for the 2019 season is
410 **2.9 mg m⁻³.**

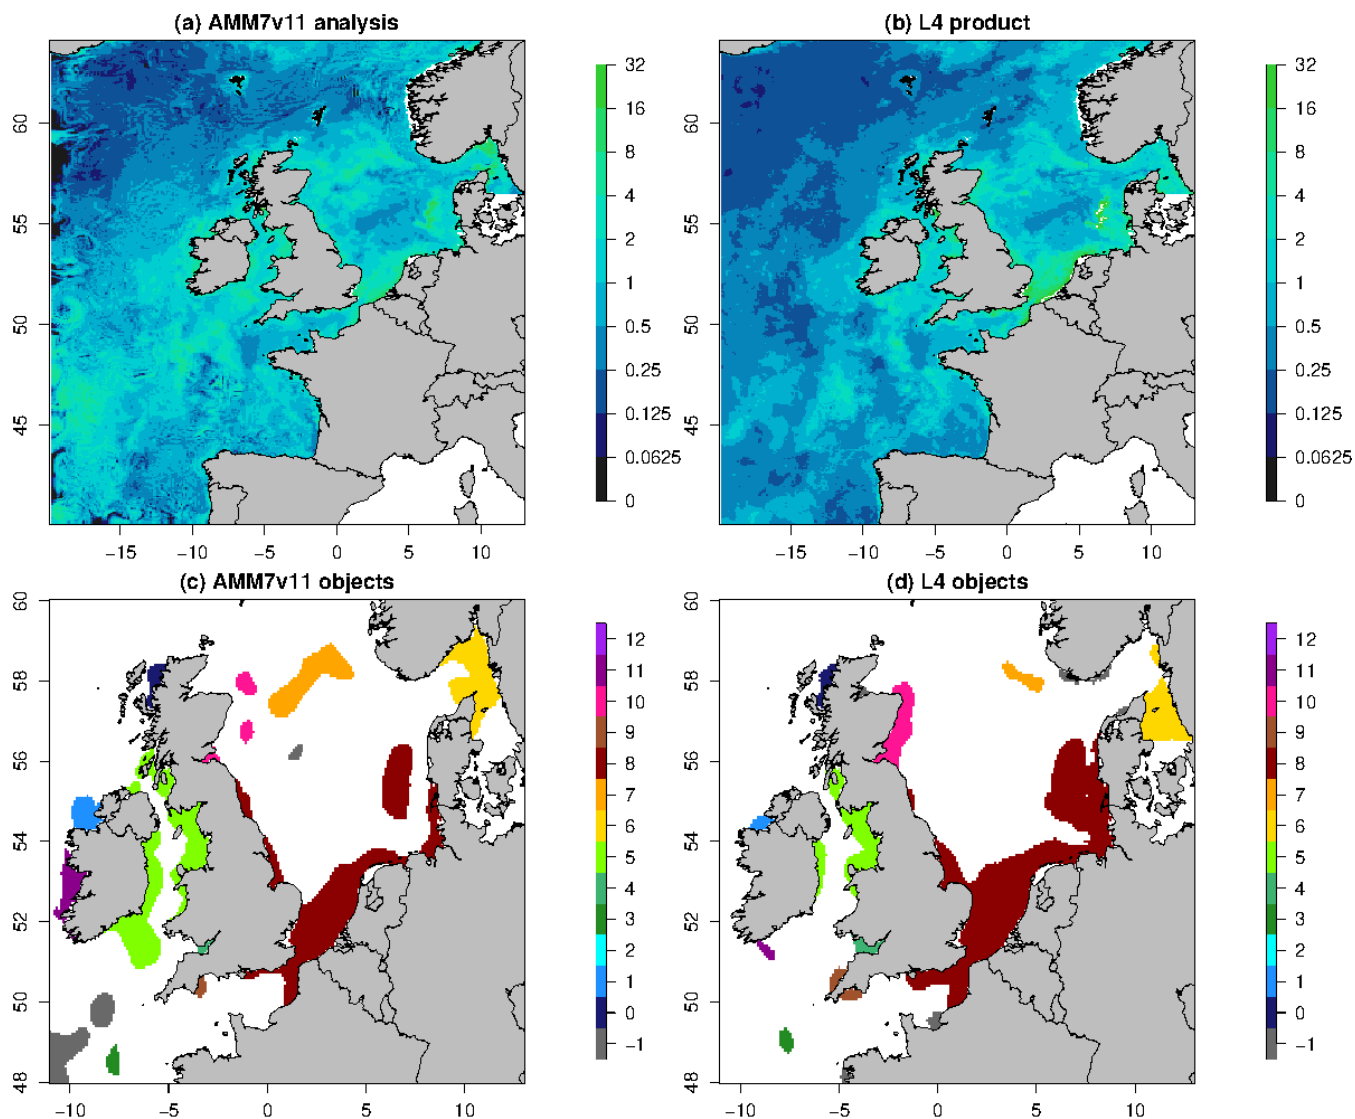

411 In employing a threshold-based approach, generally the same threshold is applied to both data sets. In
412 the presence of a bias this requires a little bit of thought. In extreme cases, it could mean the inability to
413 identify objects in one of the data sets, which would then mean objects cannot be matched and paired,
414 negating the purpose of a spatial method like MODE or MTD. Not being able to identify any objects
415 does provide some useful information, though arguably not enough context. The lack of objects does
416 suggest the presence of a bias, but it does not provide any sense of whether the model is producing a
417 constant value of Chl-*a* for example, which would be of no use to the user, or whether it does capture
418 regions of enhanced Chl-*a*, albeit with an offset which means it does not exceed the set threshold.
419 Therefore, a more likely scenario is that a bias could partially mask relevant signals in the derived
420 object properties, which could lead to the potential misinterpretation of results. If there is a significant

421 risk of this occurring the bias could be addressed before features are identified to ensure that the
422 primary purpose of using a feature-based assessment can be achieved, i.e. identifying features of interest
423 in two sets of fields to assess their location, timing and other properties and assessing their skill. The
424 fact that there is an intensity offset should not prevent the method from providing information about the
425 skill of identified features. As is seen here, though there is bias (as seen in [Figure 4](#) and [Figure](#)
426 [5](#)), it does not prevent the method from successfully identifying objects using the same threshold
427 for both datasets, though it will be shown that the effect of the bias can affect some object attributes,
428 e.g. object areas. However, a more prohibitive bias could compromise the methods, e.g., being unable to
429 identify objects in a dataset. This would have a disproportionate effect on the statistics for the matched
430 pairs in particular. Under such circumstances the quantile mapping functionality within MODE (to
431 remove the effect of the bias) is strongly recommended.

432 **4.3 Visualising daily objects**

433 [Figure 6](#) shows the daily Chl-*a* concentration fields as represented in the L4 ocean colour
434 product and the AMM7v11 analyses for 21 April 2019, which is near the peak of the bloom season. The
435 respective fields are plotted in (a) and (b), noting that the 1 km resolution L4 product has been
436 interpolated onto the ~7 km AMM7 grid. Applying a threshold of 6.3 mg m⁻³ to both with a smoothing
437 radius of ~21 km (3 grid lengths) yields 8 objects in the AMM7v11 analysis (7 visible in this zoomed
438 region) and 11 objects in the L4 product. As discussed, the bias described in Section 4.1 does not appear
439 to prevent the identification of objects in the L4 product and the AMM7v11 analyses, and the process of
440 finding matches is possible.

441

442
 443 **Figure 6 Daily Chl-*a* concentrations (in mg m^{-3}) for 21 April 2019: (a) AMM7v11 analysis and (b) L4 ocean colour**
 444 **product. The MODE objects shown in (c) and (d) are identified using a threshold of 6.3 mg m^{-3} and a smoothing**
 445 **radius of $\sim 21 \text{ km}$. Note (c) and (d) show a smaller (inner) domain. The colours show the matching clusters. Objects**
 446 **denoted with -1 (grey) are unmatched.**

447 4.4 Spatial characteristics

448 This section demonstrates the kinds of results that can be extracted from the two-dimensional MODE
 449 objects. Aspects of the marginal (AMM7v11 or L4 product only) and joint (matched/paired)

450 distributions can be examined. This includes object size (as a proxy for area) but also the proportion of
451 areas that are matched or unmatched.

452

453 Firstly, how similar is the L4 ocean colour product and the AMM7v11 analysis in terms of the features
454 of most interest, i.e., the Chl-*a* blooms? ~~Figure 7~~ Figure 7 shows the evolution of the proportion of
455 matched object areas (to total combined area) through the 2019 season, when using MODE to compare
456 the L4 product and AMM7v11 analyses, to further explore the differences (and similarities) between
457 them. A value of one would ~~suggest~~ indicate that all identified areas are matched. Values less than one
458 suggest that some objects remain unmatched. The relatively high values of matched object-to-total area
459 during April are due to the large numbers of well-matched, physically small coastal objects in addition
460 to the larger Chl-*a* bloom originating in the Dover Straits (not shown). There is a notable minimum at
461 the beginning of July. Inspecting the MODE graphical output reveals this is in part due to only a few
462 small objects being identified, and this is compounded by their complete mismatch; the L4 objects are
463 all coastal, whilst the AMM7v11 objects are either coastal (but not in the same location as L4 objects)
464 or in the deep waters of the North Atlantic, to the north-west of Scotland. The relatively high
465 proportions either side of this time arise from a better correspondence in placement of the coastal
466 objects (noting that there is a distance limit on how far objects can be apart for the matching process to
467 have a positive contribution to the interest score).

468

469 **Figure 7 Proportion of total object area which is matched. Underlying matched and unmatched object areas (in units**
 470 **of numbers of grid squares) are taken from the MODE output. These areas are for the 2.5 mg m⁻³ concentration**
 471 **threshold objects.**

472 Overall, the AMM7v11 analysis is similar, but clearly not identical, to the L4 product. Best
 473 correspondence appears to be during the first half of the bloom season. Later in the season the model's
 474 determination to produce blooms in deep North Atlantic waters is a model deficiency that the
 475 assimilation is (at this stage) unable to fix. The AMM7v11 analyses could conceivably be used as a
 476 credible source for assessing the AMM7 Chl-*a* forecasts in the future. The major benefit of using a
 477 model analysis is that it is at the same spatial resolution, with the same ability to resolve Chl-*a* bloom
 478 objects, especially along the coast (i.e. the analysis limits the uncertainty due to whether an object could
 479 be missing due to the inability of the model to resolve the feature).

480

481 The day-to-day number of objects identified through the 2019 bloom season is shown in [Figure 8](#)
 482 [Figure 8](#), illustrating how elements of the marginal and joint distribution provided by MODE can be used
 483 together. Here, numbers of total and matched (joint) objects are shown. If the AMM7v11 analyses are

484 good (i.e., similar to the L4 product), there should be fewer unmatched (marginal) objects than matched
485 ones (indicated by the proximity of the solid and dashed lines); ideally there would be no unmatched
486 objects in either the L4 product or the AMM7v11 analysis. In ~~Figure 8~~ [Figure 8](#) the number of objects in
487 AMM7v11 starts off small and increases as the bloom develops. For the L4 product there are already
488 many objects identified at the start of the timeseries, leading to many unmatched L4 objects (these could
489 be considered misses in a more categorical analysis). A spike in the number of matched objects seen in
490 early April can be attributed to several coastal locations, which appear to be spatially well-matched. In
491 addition, a larger Chl-*a* bloom is seen in the Dover Straits region in the L4 product and although not
492 exactly spatially collocated, the objects are matched. There are a consistently large number of
493 unmatched objects seen in the AMM7v11 analysis and L4 ocean colour product from the end of May
494 onwards. In the AMM7v11 analysis this appears to be due to an increase in small objects identified,
495 mainly to the west, north and east of the United Kingdom. The increase in unmatched objects in the L4
496 ocean colour product is of a different origin, being due to an increase in localised coastal blooms.
497 Generally, the AMM7v11 analyses do not have the resolution to resolve these. Overall, there are 2632
498 AMM7v11 bloom objects identified in the season using the 2.5 mg m⁻³ threshold, and 2341 L4 bloom
499 objects, with 56% of AMM7v11 objects matched and 59% of L4 objects matched.

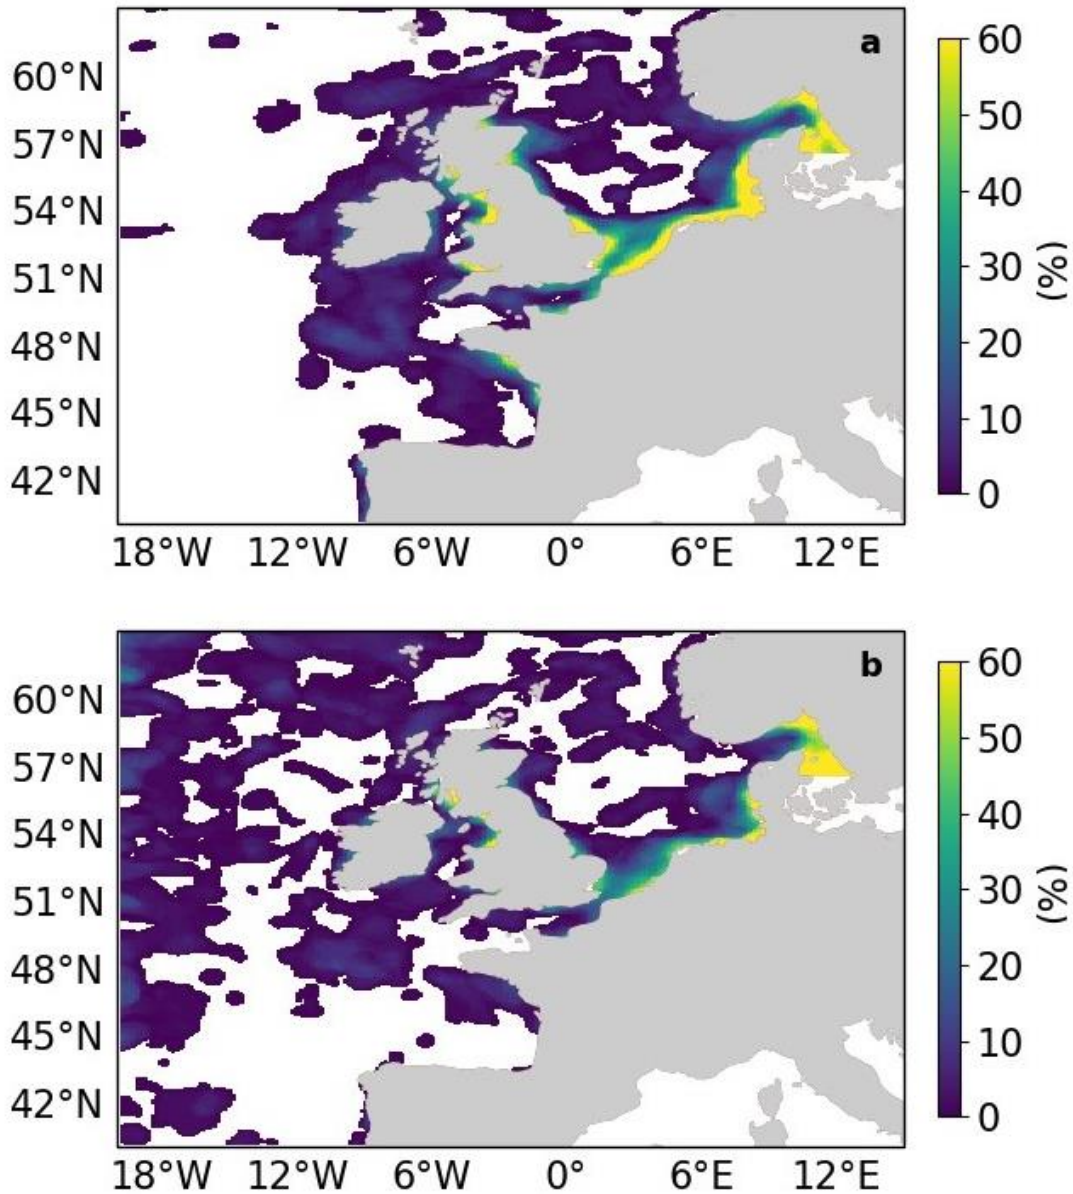

500 The identified objects in AMM7v11 and the L4 product can also be considered spatially over the season
501 by compositing the objects. This is done by counting the frequency with which a given grid square falls
502 within an identified object on any given day, essentially creating a binary map. These can be added up
503 over the entire season to produce a spatial composite object or temporal “frequency-of-occurrence” plot.

504

505 **Figure 8** Time series of the number of matched and total objects per day from MODE comparing AMM7v11 analyses
 506 (black) with L4 satellite product (grey). Objects are identified using a threshold of 2.5 mg m^{-3} . Total object numbers
 507 for the season are 2341 for L4 satellite product and 2632 for AMM7v11.

508 Figure 9 shows this spatial composite for the 2019 bloom season for the L4 ocean colour
 509 product objects (a) and the AMM7v11 objects (b). These are the composites based on the 2.5 mg m^{-3}
 510 threshold objects. There are areas, for example in the South West Approaches (SWA, see Figure
 511 3), where there appears to be a good level of consistency. AMM7v11 analyses have elevated
 512 Chl-*a* values along the northern and western edges of the domain, for a low proportion of the time,
 513 which are not seen in the L4 product. This is likely due to the way that nutrient and phytoplankton
 514 boundary conditions are specified in AMM7v11. Overall, the low temporal frequency extent of the
 515 AMM7v11 objects is greater than for the L4 product.

516

517 **Figure 9 Object composites (the proportion of time for which an object was present at the grid box throughout the**
 518 **2019 bloom season) for (a) the L4 ocean colour product objects and (b) the AMM7v11 analysis objects.**

519 Thus far all the attributes have been based on only the AMM7v11 or L4 objects. The distribution of
 520 object properties, derived for the season from the daily comparisons, can be summarised using box-and-
 521 whisker plots. Recall that the box encompasses the inter-quartile range (IQR, 25th to 75th quantile) and

522 the notch and line through the box denotes the median or 50th quantile. The dashed line represents the
523 mean, and the whiskers show ± 1.5 times the IQR. For clarity, values outside that range have been
524 filtered out of the plots shown here. ~~Figure 10~~Figure 10 shows the intersection-over-area paired object
525 attribute distribution as box-and-whisker plots for all object pairs during the 2019 bloom season,
526 comparing the AMM7v11 analyses to L4 for three of the thresholds: 2.5 and 4.0 and 6.3 mg m⁻³. The
527 intersection-over-area diagnostic gives a measure of how much the matched (paired) objects overlap in
528 space. If the objects do not intersect, this metric is 0. The ratio is bounded at 1 because any area of
529 overlap is always divided by the larger of the two object areas. The IQR for the 2.5 mg m⁻³ threshold is
530 0.25 with 50% of paired objects having an intersection-over-area of 0.97 or greater. However, the lower
531 whisker spans a large range of values to as low as 0.375, suggesting that there is a proportion of object
532 pairs with only small overlaps. There is quite a difference between the median (notch) and the mean
533 (dashed line) for this metric, suggesting the distribution is skewed with the mean affected more by many
534 small overlaps. For the 4.0 mg m⁻³ threshold paired objects the intersection-over-area distribution is
535 much broader, though the difference between the mean and medians is similar. The proportion of paired
536 objects with smaller overlaps has also increased. This should not be surprising given that the objects
537 generally get smaller with increasing threshold such that the ability for object pairs to overlap actually
538 decreases unless they are very closely collocated. At the 6.3 mg m⁻³ threshold the median is lower
539 (0.93) with a similar difference from the mean, however the sample size is much smaller (only 130
540 paired objects over the season).

541

542 **Figure 10** Box-and-whisker plots of the paired object property “intersection area” ratio computed by dividing the spatially
 543 collocated area between the paired objects by the largest of either the AMM7v11 or L4 observed object areas (to keep the ratio to
 544 be bounded by 0 and 1). Three object thresholds are shown: $2.5 \text{ mg} \cdot \text{m}^{-3}$, $4.0 \text{ mg} \cdot \text{m}^{-3}$ and $6.3 \text{ mg} \cdot \text{m}^{-3}$. Smoothing radii of 5, 5 and 3
 545 grid lengths were applied for the three thresholds respectively. The sample sizes for each threshold were 1004, 401 and 130 paired
 546 objects respectively.

547

548 **4.5 Incorporating the time dimension**

549

550 Having information in space *and* time enables one to ask, and hopefully answer questions such as: “*did*
 551 *the model predict the bloom to start in the observed location?*” or “*did the model predict the onset at*
 552 *the right time?*” and “*did the model predict the peak (in terms of extent) and duration of the bloom*
 553 *correctly?*”.

554

555 MTD identifies objects in space and time. As previously described, all MTD results are based on a 2.5
 556 $\text{mg} \cdot \text{m}^{-3}$ threshold applied to both the L4 ocean colour products and AMM7v11 analyses. A time
 557 centroid is derived from a time series of the spatial (two-dimensional) centroids which are computed for
 558 each (daily) time slice. In addition to this, each identified MTD object has a start and end time, and a

559 geographical location of the time centroid, which is the average of the two-dimensional locations. The
560 time component of the time centroid is weighted by volume.
561

562 The temporal progression of the 2019 bloom season along with spatial information as defined by the
563 MTD objects' is shown in ~~Figure 11~~Figure 11. The object start- and end times as well as the date of
564 their time centroids in (a) provide a clear view of the onset and demise of each object (bloom episode).
565 In total there are 22 AMM7v11 and 11 L4 MTD objects. The x-axis in (a) represents elapsed time. The
566 location of the vertical lines along the x-axis on any given date indicates the date of the time centroid
567 whilst the duration of the space-time object can be gleaned from the y-axis based on the start and end of
568 the vertical line which defines the time the object was in existence. Solid lines represent the L4 product
569 objects whereas dashed lines represent the AMM7v11 objects. The colour palette is graduated from
570 grey and blue through green, yellow, red, and purple, denoting the relative time in the season. In (a) the
571 first Chl-*a* bloom object in the AMM7v11 analysis was identified on 29 March 2019 whereas in the L4
572 ocean colour product the first bloom object was identified on 3 March, 26 days earlier. The first time
573 the L4 product and AMM7v11 analyses have concurrent objects (blooms) is in late March. The L4
574 product also suggests that the season ends 30 June whereas the AMM7v11 analyses persists the bloom
575 season with objects identified until 23 July. Most AMM7v11 objects are of relatively short duration, but
576 overall, most groups of AMM7v11 objects have some temporal association with an L4 product object
577 around the same time. In this instance it is also illuminating to consider the daily object areas
578 associated with the MTD objects (which are used to compute the volume of MTD objects). These are
579 plotted in ~~Figure 11~~Figure 11(b) showing all daily L4 object areas in the filled circles, and the
580 AMM7v11 object areas (crosses), in the same colours as in (a). The main purpose is to highlight the
581 relative size of the L4 and AMM7v11 objects on any given day, as well as how many objects there
582 were. Recall that these are the objects identified using a Chl-*a* concentration threshold of 2.5 mg m⁻³.
583 Some of the AMM7v11 objects are considerably larger than those in L4 in the mid- and latter part of the
584 bloom season from mid-May onwards, just not necessarily at exactly the same time or location. As seen
585 in ~~Figure 11~~Figure 11(b), the area time series also illustrates the offsets in the start and end of the bloom
586 season. Some of the objects detected in AMM7v11 beyond the end of the observed bloom season

587 provided by L4, suggests that at least three substantial areas are still diagnosed to exceed the threshold
588 of 2.5 mg m^{-3} into July. Taking the start of the earliest space-time object as the onset of the bloom
589 season and the end of the last object as the end, the 2019 season is 119 days long based on the L4
590 product, and 117 days in the AMM7v11 analysis. Therefore, the overall length of the season as defined
591 by the space-time objects is comparable in the AMM7v11 analysis, albeit with a substantial offset.
592 Finally, even if (a) and (b) suggest that AMM7v11 and L4 objects exist at the nearly the same time, this
593 does not mean they are geographically close to each other. This is illustrated in [Figure 11](#)~~Figure 11~~(c)
594 which provides the spatial context. The colours and symbols are consistent across all panels and show
595 that even when the MTD objects are identified at the same time they may be geographically quite far
596 apart, or more typically there is no L4 counterpart (filled circle) to an AMM7v11 bloom object (cross).
597 The north- and westward progression of the bloom as the season unfolds can be seen through the use of
598 the colours, with the AMM7v11 analysis producing enhanced Chl-*a* concentrations in deeper waters to
599 the north and west of the domain beyond the end of the observed season.

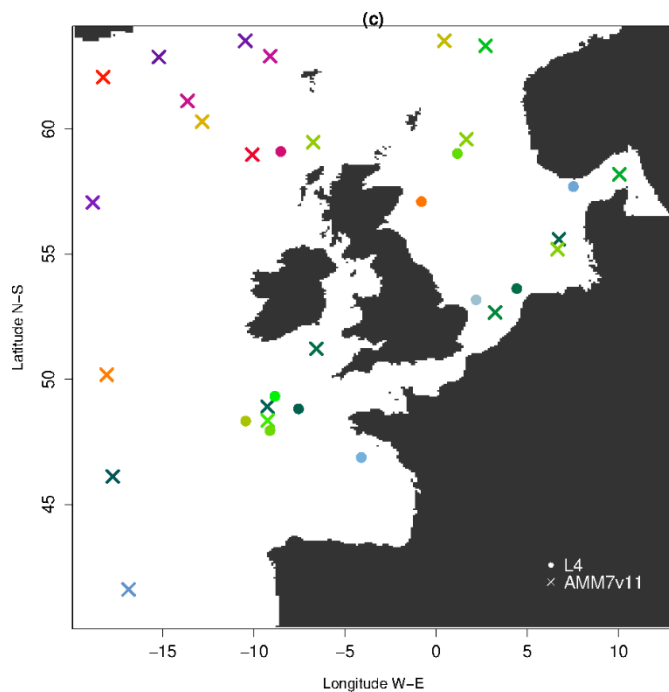

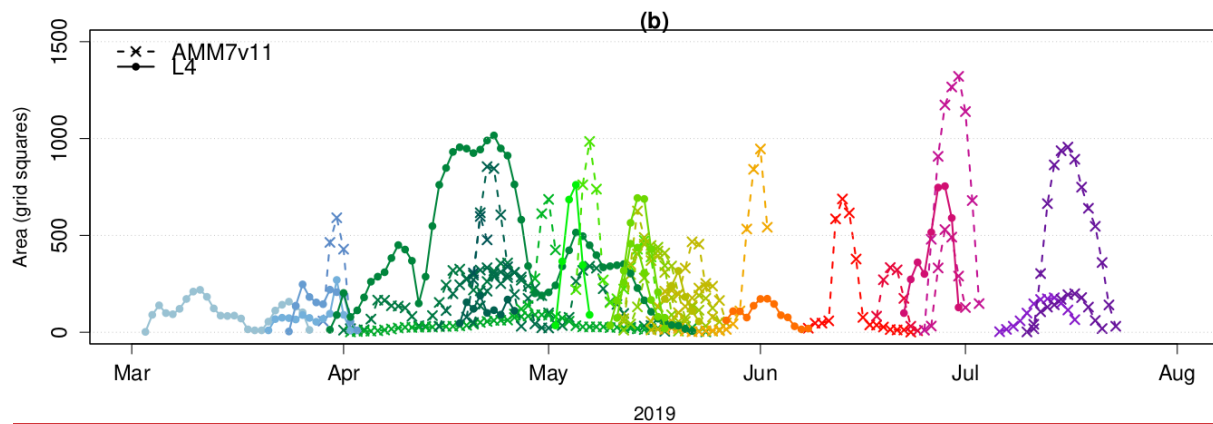

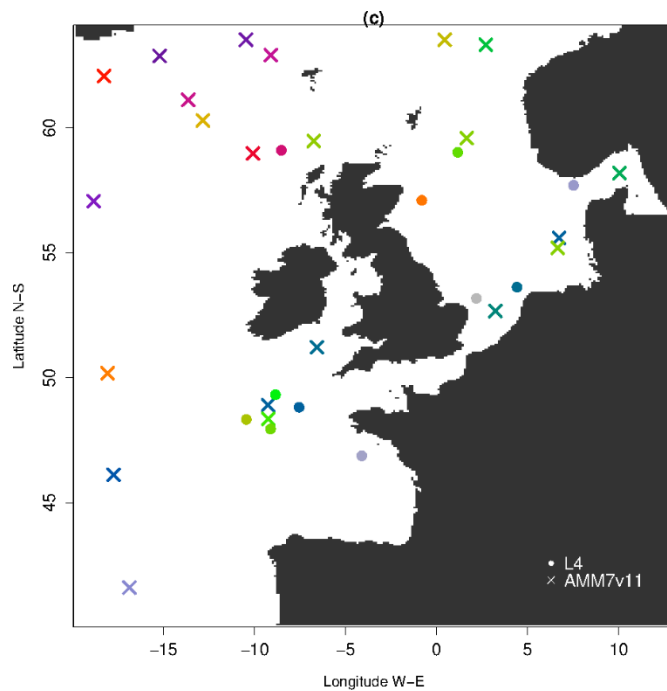

Figure 11 Space-time information from the L4 (filled circle) and AMM7v11 (cross) MTD objects. (a) The timing of each identified bloom event (time centroid) plotted on the x-axis against the duration of the bloom event, denoted by the vertical line which represents the start and end time of each space-time object. (b) Daily object areas. (c) Spatial location of the time centroid shown in (a) to indicate that even if AMM7v11 and L4 objects exist at the same time they may not be geographically close. Colours are coordinated across all panels.

600 With only 22 AMM7v11 and 11 L4 product MTD objects, which are temporally and geographically
 601 well dispersed, three of the L4 objects remained unmatched, leaving only 8 matched MTD objects for
 602 the 2019 bloom season with an overall interest score greater than 0.5. This represented an insufficient
 603 sample for drawing any robust statistical conclusions. Nevertheless, some inspection of the paired MTD
 604 object attributes are summarised below:

- 605 • The spatial centroid (centre of mass) differences can be extensive, but the majority are within 0 to
 606 100 grid squares apart (i.e. up to ~700 km).
- 607 • The majority of paired objects have time centroid differences +/- 10 days.
- 608 • Considering the volumes of the space-time objects, half the paired objects have volume ratios of less
 609 than 1, i.e. AMM7v11 objects tend to be smaller or similar in size. The other pairs have ratios as
 610 high as 4.
- 611 • Overlaps between AMM7v11 and L4 MTD objects remain small and infrequent with only one pair
 612 with a significant overlap in space and time.

613 5. Discussion and conclusions

614 The traditional statistics provided in Table 1 give useful insights into overall performance, but even
615 when the full domain is divided into sub-regions, they do not focus on the events of interest enough to
616 provide more detailed information on the evolution of bloom events as the season progresses.

617

618 MODE and MTD, two distinct but related feature-based diagnostic verification methods, provide more
619 detailed diagnostic information in space and time. This was demonstrated by using these two methods
620 to evaluate and compare ~~MODE and MTD were used as two distinct but related feature-based~~
621 ~~diagnostic verification methods to evaluate and compare~~ the pre-operational AMM7v11 European
622 North West Shelf Chl-*a* concentration bloom objects to those identified in the satellite-based L4 ocean
623 colour product. Nominally blooms were said to occur when the concentration threshold exceeded 2.5
624 mg m⁻³ and two higher thresholds were also considered. Sample sizes dwindle rapidly with increasing
625 threshold. Of specific interest were the similarities and differences in respective bloom object sizes,
626 their geographical location and collocation and timing. For the timing component the onset, duration,
627 and demise of individual bloom objects (events) could be considered. For the season all the identified
628 space-time objects provided an estimate of the onset, duration and end of the bloom season as a whole.
629 The season was found to be of similar length, but the onset was found to begin 26 days later in the
630 AMM7v11 analyses than in the L4 product, and the AMM7v11 analyses persist the season for almost a
631 month beyond the diagnosed end identified in the L4 product. Using traditional verification methods,
632 data assimilation has been shown to considerably reduce the delay in bloom onset in the model (Skákala
633 et al., 2020). Using feature-based verification methods, this study suggests that a substantial delay still
634 remains.

635

636 There is a modest concentration bias in the AMM7v11 analyses compared to the L4 satellite ocean
637 colour product. In this study we chose not to mitigate against this bias as it was not considered to
638 impede the identification of bloom objects, which would prevent the ability of the methodology to
639 identify matches and create paired object statistics. Any concentration bias does affect the results and
640 this effect must be understood or at least kept in mind when interpreting results, in this case it will have

641 contributed to the result that the AMM7v11 bloom objects are generally larger. An alternative approach
642 would be to mitigate against the impact of the bias before using a threshold-based methodology such as
643 MODE or MTD. A quantile mapping approach is available within the MODE tool (not yet available in
644 MTD but should be available at some point) to remove the biases between two distributions as each
645 temporal data set is analysed. Using this method, the one threshold is fixed, and the other threshold
646 varies day-to-day (as shown in ~~Figure 5~~[Figure 5](#)). Another approach would be to analyse the bias for the
647 whole season (as shown in ~~Figure 4~~[Figure 4](#)) and deriving an equivalent threshold from this larger data
648 set, thus applying a fixed threshold to all the days in the season, though there would still be two
649 different thresholds applied to the two data sets.

650

651 MODE results suggest that the AMM7v11 bloom objects are larger than those in the L4 product.
652 AMM7v11 produces more objects (in number) than seen in the L4 ocean colour product, yet many of
653 the coastal objects seen in the L4 product are not as well resolved in AMM7v11 due to the coarseness of
654 the coastline in the 7 km model. The additional AMM7v11 objects are mainly found in deeper Atlantic
655 waters. The diagnosis of coastal blooms should improve if the model resolution were increased from
656 7 km to 1.5 km.

657

658 Using MODE and MTD clearly gives extra information not obtained from traditional verification
659 metrics that are more routinely used (McEwan et al., 2021). An alternative approach to assessing the
660 representation of phytoplankton blooms might be to use phenological indices (Siegel et al., 2002;
661 Soppa, et al., 2016), which measure the day of the year on which Chl-*a* concentration first crosses a
662 threshold based on the median concentration. Phenological indices have been used in observation [and](#)
663 [model-based](#) process studies (e.g. [Racault et al., 2012](#); [Pefanis, 2021](#)), but ~~very~~ rarely for model
664 verification, and then ~~only usually~~ in 1D (Anugerahanti et al., 2018) [or at low temporal resolution](#)
665 (Hague and Vichi, 2018) ~~(Hague and Vichi, 2018)~~. One reason for this is that daily model Chl-*a* will
666 frequently cross such a threshold throughout the bloom season, meaning temporal smoothing and other
667 processing (Cole et al., 2012) would be required, which is not straightforward to apply consistently.

668 Objective methods such as MODE and MTD, which consider individual bloom objects throughout the
669 season, rather than assuming a single spring bloom will occur at each location, bypass these difficulties.
670
671 Other work that formed part of this study, but is not reported on here, showed that constraining the Chl-
672 *a* using assimilation of the satellite observations appears to benefit the model in terms of fewer
673 unmatched bloom regions. This should translate to an improvement in the forecasts generated from this
674 analysis compared with previous versions of the operational system and will be the subject of future
675 work.

676 **6. Code availability**

677 Model Evaluation Tools (MET) was initially developed at the National Center for Atmospheric
678 Research (NCAR) through grants from the National Science Foundation (NSF), the National Oceanic
679 and Atmospheric Administration (NOAA), the United States Air Force (USAF) and the United States
680 Department of Energy (DOE). The tool is now open source and available for download on github:
681 <https://github.com/dtcenter/MET>. For this study MET version 8.1 of the software was used. MET
682 allows for a variety of input file formats but some pre-processing of the CMEMS NetCDF files was
683 necessary before the MODE package could be applied. This includes regridding of the observations
684 onto the model grid, and addition of the forecast reference time variables to the NetCDF attributes. All
685 aspects on the use of MET are provided in in the MET software documentation available online at
686 <https://dtcenter.github.io/MET>.

687 **7. Data availability**

688 Data used in this paper was downloaded from the Copernicus Marine and Environment Monitoring
689 Service (CMEMS). The datasets used were:

- 690 • [https://resources.marine.copernicus.eu/?option=com_csw&task=results?option=com_csw&view=de](https://resources.marine.copernicus.eu/?option=com_csw&task=results?option=com_csw&view=details&product_id=OCEANCOLOUR_ATL_CHL_L4_NRT_OBSERVATIONS_009_037)
691 [tails&product_id=OCEANCOLOUR_ATL_CHL_L4_NRT_OBSERVATIONS_009_037](https://resources.marine.copernicus.eu/?option=com_csw&task=results?option=com_csw&view=details&product_id=OCEANCOLOUR_ATL_CHL_L4_NRT_OBSERVATIONS_009_037) (last
692 access: August 2019),

- 693 • https://resources.marine.copernicus.eu/?option=com_csw&view=details&product_id=NORTHWES
694 [TSHELF ANALYSIS FORECAST BIO 004 002 b](#) (last access: August 2019)

695

696 The AMM7v11 analyses were not operational at the time of this study and not yet available from the
697 CMEMS server.

698 **8. Author contribution**

699 All authors contributed to the introduction, data and methods, and conclusions. MM, RN, JM and CP
700 contributed to the scientific evaluation and analysis of the results. MM and RN designed and ran the
701 model assessments. CP supported the assessments through the provision and reformatting of the data
702 used. DF provided detail on the model configurations used.

703 **9. Competing interests**

704 The authors declare that they have no conflict of interest.

705

706 **10. Acknowledgements**

707 This study has been conducted using E.U. Copernicus Marine Service Information.

708

709 This work has been carried out as part of the Copernicus Marine Environment Monitoring Service
710 (CMEMS) HiVE project. CMEMS is implemented by Mercator Ocean International in the framework
711 of a delegation agreement with the European Union.

712

713 We would like to thank the National Center for Atmospheric Research (NCAR) Developmental Testbed
714 Center (DTC) for the help received via their met_help facility in getting MET to work with ocean data,
715 and Robert McEwan (Met Office) for his assistance with the production of the traditional metrics.
