**Abstract:** Microplastics (MPs) are a contaminant of growing concern due to their widespread 13 distribution and interactions with marine species, such as filter feeders. To investigate the MPs 14 accumulation by wild and cultured mussels, a Dynamic Energy Budget (DEB) model was 15 16 developed and validated with the available field data of Mytilus edulis (wild) from the North Sea and Mytilus galloprovincialis (cultured) from the Northern Ionian Sea. Towards a generic DEB 17 18 model, the site-specific model parameter, half saturation coefficient  $(X_k)$  was applied as a power 19 function of food density for the cultured mussel, while for the wild it was calibrated to a constant value. The DEB-accumulation model simulated the uptake and excretion rate of MPs, taking into 20 account environmental characteristics (temperature and chlorophyll-a). An accumulation of MPs 21 equal to 0.64 particles individual<sup>-1</sup> (fresh tissue mass 1.9 g) and 0.91 particles individual<sup>-1</sup> (fresh 22 23 tissue mass 3.4 g) was found for the wild and cultured mussel respectively, in agreement with the field data. The inverse experiments investigating the depuration time of the wild and cultured 24 25 mussel in a clean from MPs environment showed a 90% removal of MPs load after 3 and 14 days, respectively. Furthermore, sensitivity tests on model parameters and forcing functions highlighted 26 27 that besides MPs concentration, the accumulation is highly depended on temperature and chlorophyll-a of the surrounding environment. For this reason, an empirical equation was found 28 29 relating directly the concentration of MPs in seawater, with MPs accumulation in mussel's soft tissue, temperature and chlorophyll-a. 30

### 32 **1. Introduction**

33

34 Microplastic particles (MPs) are synthetic organic polymers with size below 5 mm (Arthur et 35 al., 2009) that originate from a variety of sources including mainly: those that are manufactured for 36 particular household or industrial activities, such as facial scrubs, toothpastes and resin pellets used in the plastic industry (primary MPs), and those formed from the fragmentation of larger plastic 37 items (secondary MPs) (GESAMP, 2015). Eriksen et al. (2014) estimated that more than 5 trillion 38 39 microplastic particles, weighing over 250,000 tons, float in the oceans. Due to their composition, 40 density and shape, MPs are highly persistent in the environment and are, therefore, accumulating in different marine compartments at increasing rates: surface and deeper layers in the water column, as 41 42 well as at the seafloor and within the sediments (Moore et al., 2001, Lattin et al., 2004, Thompson, 2004, Lusher, 2015). Since the majority of MPs entering the marine environment, originate from the 43 44 land (i.e. land-fills, littering of beaches and coastal areas, rivers, floodwaters, untreated municipal 45 sewerage, industrial emissions), the threat of MPs pollution in the coastal zone puts considerable 46 pressure on the coastal ecosystems (Cole et al., 2011, Andrady, 2011). In recent years, initiatives 47 under various projects (i.e. CLAIM, DeFishGear) target at evaluating the threat and impact of marine litter pollution; the European framework of JERICO-RI focuses on a sustainable research 48 infrastructure in the coastal area to support the monitoring, science and management of coastal 49 marine areas (http://www.jerico-ri.eu/). In the framework of JERICO-NEXT, a recent study 50 addressed the environmental threats and gaps in monitoring programmes in European coastal 51 52 waters, including the marine litter (i.e. MPs) as one of the most commonly identified threat to the marine environment and highlighted the need for improved monitoring of the MPs distribution and 53 their impacts in European coastal environments (Painting et al., 2019). 54

Numerous studies have revealed that MPs are ingested either directly or through lower trophic 55 prey by animals from all levels of the food web; from zooplankton (Cole et al., 2013), small pelagic 56 57 fishes and mussels (Digka et al., 2018a) to mesopelagic fishes (Wieczorek et al., 2018) and large predators like tuna and swordfish (Romeo et al., 2015). Microplastic ingestion by marine animals 58 59 can potentially affect animal health and raises toxicity concerns, since plastics can facilitate the transfer of chemical additives and/or hydrophobic organic contaminants to biota (Mato et al., 2001, 60 61 Rios et al., 2007, Teuten et al., 2007, 2009, Hirai et al., 2011). Human, as a top predator, is also contaminated by MPs (Schwabl et al., 2019). Mussel and small fishes that are commonly consumed 62 63 whole, without removing digestive tracts, where MPs are concentrated, are among the most likely pathways for MPs to embed in the human diet (Smith et al., 2018). Especially regarding marine 64 organisms (i.e. mussels), it is notable that the levels of their contamination has been added to the 65

66 European database (www.ecsafeseafooddbase.eu) as an environmental variable of growing concern, 67 reflecting the health status (Marine Strategy Framework Directive (MSFD) Descriptor 10 - Marine Litter (Decision 2017/848/EU)) (De Witte et al., 2014, Vandermeersch et al., 2015, Digka et al., 68 69 2018a). Today, a series of studies have denoted the presence of MPs in mussels' tissue intended for 70 human consumption (Van Cauwenberghe and Janssen, 2014, Mathalon and Hill, 2014, Li et al., 71 2016, 2018, Hantoro et al., 2019). For instance, in a recent study, Li et al. (2018) sampled mussels 72 from coastal waters and supermarkets in the U.K and estimated that a plate of 100g mussels 73 contains 70 MPs that will be ingested by the consumer. The presence of MPs in mussels has been also demonstrated during laboratory trials in their faeces, intestinal tract (Von Moos et al., 2012, 74 75 Van Cauwenberghe et al., 2015, Wegner et al., 2012, Khan and Prezant, 2018), as well as in their circulatory system (Browne et al., 2008). Other laboratory studies showed several effects of 76 77 microplastic ingestion in laboratory exposed mussels, including histological changes, inflammatory responses, immunological alterations, lysosomal membrane destabilization, reduced filtering 78 activity, neurotoxic effects, oxidative stress effects, increase in hemocyte mortality, dysplasia, 79 genotoxicity and transcriptional responses (reviewed by Li et al., 2019). However, the tested 80 81 concentrations of MPs in laboratory experiments are frequently unrealistic, being several orders of 82 magnitude higher (2 to 7 orders of magnitude) than the observed seawater concentrations (Van 83 Cauwenberge et al., 2015, Lenz et al. 2016).

Mussels, through their extensive filtering activity, feed on planktonic organisms that have 84 similar size with MPs (Browne et al., 2007) and considering also their inability to select particles 85 with high energy value (i.e. phytoplankton) during filtration (Vahl, 1972, Saraiva et al., 2011a), 86 they are directly exposed to MPs' contamination. Recent studies suggest a positive linear 87 88 correlation between MPs concentration in mussels and surrounding waters (Capolupo et al., 2018, Qu et al. 2018, Li et al. 2019). The filtering activity of mussels, which directly affects the resulting 89 90 MPs accumulation, is a complicated process that is controlled by other factors (food availability, 91 temperature, tides etc.).

92 The purpose of the present work is to study the accumulation of MPs by the mussel and reveal 93 relations between accumulated concentrations in mussels' soft parts and environmental features. In 94 this context, an accumulation model was developed based on Dynamic Energy Budget theory (DEB, Kooijman, 2000) and applied in two different regions, in two different modes of life (wild 95 and cultivated): in the North Sea (M. edulis, wild) and in the Northern Ionian Sea (M. 96 galloprovincialis, cultivated). DEB theory provides all the necessary detail to model the feeding 97 processes and aspects of the mussel metabolism, taking into account the impact of the 98 environmental variability on the simulated individual. Apart from modeling the growth of bivalves 99 (Rosland et al., 2009, Sara et al., 2012, Thomas et al., 2011, Saraiva et al., 2012, Hatzonikolakis et 100

al., 2017, Monaco & McQuaid, 2018), DEB models have been used to study other processes as
well, such as bioaccumulation of PCBs (Polychlorinated Biphenyls) and POPs (Persistent Organic
Compounds) (Zaldivar, 2008), trace metals (Casas and Bacher, 2006) and the impact of climate
change on individual's physiology (Sara et al., 2014). However, to our knowledge this is the first
time that a DEB-based model is used to assess the uptake and excretion rates of MPs in mussels.

107

### **2. Materials and Methods**

109

#### 110 2.1 Study areas and field data

111

The North Sea is a large semi-enclosed sea on the continental shelf of north-west Europe with 112 a total surface area of  $850,000 \text{ km}^2$  and is bounded by the coastlines of 9 countries. The sea is 113 shallow (mean depth 90 m), getting deeper towards the north (up to 725 meters) and the semi-114 115 diurnal tide (tidal range 0-5 m) is the dominant feature of the region (Otto et al., 1990). Major rivers, such as Rhine, Elbe, Weser, Ems and Thames discharge into the southern part of the sea 116 (Lacroix et al., 2004), making this area a productive ecosystem. In this study, the area is limited 117 along the French, Belgian and Dutch North Sea coast (N 50.98°-51.46°, W 1.75°-3.54°). This is 118 located close to harbors, where shipping, industrial and agricultural activity is high, putting 119 120 considerable pressure on the ecological systems of the region (Van Cauwenberghe et al., 2015).

121 The MPs concentration in mussels' tissue and seawater that were used to validate and force 122 the model respectively at its North Sea implementation were derived from Van Cauwenberghe et al. 123 (2015). Van Cauwenberghe et al. (2015) examined the presence of MPs in wild mussels (M. edulis), 124 and thus collected both biota and water at 6 sampling stations along the French, Belgian and Dutch 125 North Sea coast in late summer of 2011. *M. edulis* (mean shell length:  $4 \pm 0.5$  cm and wet weight 126 (w.w.):  $2 \pm 0.7$  g) and water samples were randomly collected on the local breakwaters, in order to 127 assess the MPs concentration in the organisms and their habitat. MPs were present in all analyzed samples, both organisms and water. Seawater samples (N=12) had MPs (<1mm) on average 0.4  $\pm$ 128 0.3 particles  $L^{-1}$  (range: 0.0 - 0.8 particles  $L^{-1}$ ) and *M. edulis* contained on average 0.2 ± 0.3 129 particles  $g^{-1}$ w.w. (or 0.4 ± 0.3 particles individual<sup>-1</sup>) (Van Cauwenberghe et al., 2015). The size 130 range of MPs found within the mussels was 20-90 µm (size <1 mm). 131

The Northern Ionian Sea is located in the transition zone between the Adriatic and Ionian Sea.The long and complex coastline, presents a high diversity of hydrodynamic and sedimentary

134 features. Rivers discharging into the Northern Ionian Sea include Kalamas/Thyamis (Greece) and 135 Butrinto (Albania) (Skoulikidis et al., 2009), making the area suitable for aquaculture. Small 136 farming sites and shellfish grounds are operating in Thesprotia (northwestern Ionian Sea) 137 (Theodorou et al., 2011). The main source of marine litter inputs in the area originates from anthropogenic activities that mainly include shoreline tourism and recreational activities, poor 138 wastewater management, agricultural practices, fisheries, aquacultures and shipping (Vlachogianni 139 et al., 2017; Digka et al., 2018a). According to Politikos et al. (2020), the area around the Corfu 140 island (Northern Ionian Sea) is characterized as a retention area of litter particles probably due to 141 142 the prevailing weak coastal circulation. Furthermore, a northward current on the east Ionian Sea 143 facilitates the transfer of litter particles towards the Adriatic Sea, which has been characterized as a 144 hotspot of marine litter and one of the most affected areas in the Mediterranean Sea (Pasquini et al., 145 2016, Vlachogianni et al., 2017, Liubartseva et al., 2018, Politikos et al., 2020).

The field data used to validate the model output in the N. Ionian Sea were obtained from 146 Digka et al. (2018b, 2018a). In the framework of the "DeFishGear" project, mussels (M. 147 galloprovincialis) were collected by hand from a long line type mussel culture farm in Thesprotia 148 (N 39.606567° E 20.149421°), in summer 2015 (July) at a sampling depth up to 3 m (Digka et al., 149 2018a). The average MPs accumulation was calculated from a total population of 40 mussels 150 originated from the farm, with 18 of them found contaminated with MPs (46.25%). The average 151 152 load of MPs (size <1 mm) per mussel (mean shell length  $5.0 \pm 0.3$  cm) was  $0.9 \pm 0.2$  particles individual<sup>-1</sup> and the size of MPs found in the mussel's tissue ranged from 55 to 620 µm. Both clean 153 154 and contaminated mussels were included in the calculated mean value in order to represent the 155 mean state of the contamination level for the individual inhabiting the study area.

156 The seawater concentration of MPs for the N. Ionian Sea implementation was obtained from 157 Digka et al. (2018b) and the DeFishGear project results (http://www.defishgear.net/project/main-158 lines-of-activities). In total, 12 manta net tows were conducted in the region, collecting a total 159 number of n1=2,027 particles on October 2014 and n2=1,332 on April 2015, leading to an average 160 of 280 particles per tow with size <1 mm and >330 µm (Digka et al., 2018b). In order to estimate 161 the mean MPs concentration in the region, expressed as particles per volume, the dimensions of the 162 manta net (W 60 cm H 24 cm, rectangular frame opening, mesh size 330 µm) and the sampling distance of each tow (~2 km) were used by multiplying the sample surface of the net by the trawled 163 distance in meters (Maes et al., 2017), which resulted in a mean MPs concentration of 1.17 particles 164 m<sup>-3</sup> (233,333 particles km<sup>-2</sup>). Moreover, in the wider region of the Adriatic Sea, Zeri et al. (2018) 165 found a mean density of  $315,009 \pm 568,578$  particles km<sup>-2</sup> ( $1.58 \pm 2.84$  particles m<sup>-3</sup>), out of which 166 34% sized <1 mm. A relatively high value of standard deviation (one order of magnitude higher 167 than the mean value) is adopted  $(0.0012 \pm 0.024 \text{ particles } \text{L}^{-1})$ , considering that the mussel farm is 168

169 established in an enclosed gulf and close to the coast, since, according to Zeri et al. (2018), the 170 abundance of MPs is one order of magnitude higher in inshore (<4 km) compared to offshore 171 waters (>4 km). Furthermore, it may be assumed that the adopted range (standard deviation is also 172 multiplied by a factor of 2) includes also the smaller particles sized between 50  $\mu$ m and < 330  $\mu$ m, 173 which have been found in mussel's tissue (Digka et al., 2018a), but were overlooked during the 174 seawater sampling due to the manta net's mesh size (>  $330 \mu$ m). According to Enders et al. (2015) the relative abundance of small particles (50- 300 µm) compared to particles larger than 300 µm is 175 176 approximately 50%.

177

#### 178 **2.2 DEB model description**

179

In the present study, a Dynamic Energy Budget (DEB, Kooijman, 2000, 2010) model is used 180 181 as basis to simulate the accumulation of MPs by mussels. In DEB theory (Kooijman, 2000), the 182 energy assimilated through food by the simulated individual is stored in a reserve compartment 183 from where a fixed energy fraction  $\kappa$  is allocated for growth and somatic maintenance, with a priority for maintenance. The remaining energy  $(1 - \kappa)$  is spent on maturity maintenance and 184 reproduction. The individual's condition is defined by the dynamics of three state variables: energy 185 reserves E (joules), structural volume V (cm<sup>3</sup>) and energy allocated to reproduction R (joules). The 186 187 energy flow through the organism is controlled by the fluctuations of the available food density and 188 temperature characterizing the surrounding environment.

189 The DEB model implemented here is an extended version of the model described in 190 Hatzonikolakis et al. (2017), where the growth of the Mediterranean mussel is simulated by taking into account only the assimilation rate of the individual. Since the present study focuses on 191 192 simulating the MPs accumulation, it is crucial to include a detailed representation of the mussel's 193 feeding mechanism. In this context, the DEB model was extended by including the clearance  $(C_r)$ , 194 filtration ( $p_{XiF}$ ) and ingestion ( $p_{XiI}$ ) rates of the mussel, following Saraiva et al. (2011a), with MPs 195 represented by the silt variable. In this approach, a pre-ingestive selection occurs between filtration 196 and ingestion, returning the rejected material in the water through pseudofaeces  $(J_{pfi})$ . 197 Consequently, energy is assimilated through food while the non-assimilated particles are excreted 198 through the faeces production  $(J_{f})$ . The model's equations, variables and parameters are shown in 199 Table 1, 2 and 3 respectively. The scaled functional response f (Eq. 5, Table 1), which regulates the 200 assimilation rate, is modified following Kooijman (2006) to include an inorganic term representing the non-digestible matter i.e. microplastics:  $f = X/(X + K_v)$  and  $K_v = X_K \cdot (1 + Y/Y_K)$  where Y 201 and  $Y_k$  are the concentration of MPs, converted from particles L<sup>-1</sup> to g m<sup>-3</sup> (Everaert et al., 2018) and 202

the half saturation coefficient of inorganic particles here represented by MPs (g m<sup>-3</sup>), respectively. 203 204 Thus, the assimilation rate that is regulated by f is decreasing when the concentration of MPs is increased. The same approach is followed by other authors who considered inedible particles in the 205 mussel's diet (Ren, 2009, Troost et al., 2010). During the filtration process the same clearance rate 206 for all particles is used ( $\{\dot{C}_R\}$ ), representing the same searching rate for food that depends on the 207 organism maximum capacity ( $\{\dot{C}_{Rm}\}$ ) and environmental particle concentrations (Vahl, 1972, 208 Widdows et al., 1979, Cucci et al., 1989). During the ingestion process the mussel is able to 209 210 selectively ingest food particles and reject inedible material, in order to increase the organic content of the ingested material ((Kiørboe & Møhlenberg, 1981, Jørgensen et al., 1990, Prins et al., 1991, 211 212 Maire et al., 2007, Ren, 2009, Saraiva et al., 2011a). This selection is reflected by the different 213 binding probabilities adopted for each type of particle ( $\rho_1$  for algae particles and  $\rho_2$  for inorganic 214 particles i.e. MPs, see Eq. 14 and table 3). The equations representing the feeding processes handle 215 each type of particle separately, while there is interference between the simultaneous handling of 216 different particle types (Eq. 12-14, Table 1) (Saraiva et al., 2011a). Finally, during the assimilation 217 process, suspended matter (i.e. MPs) that the mussel is not able to assimilate due to its different 218 chemical composition from the reserve compartment (Saraiva et al., 2011a) or incipient saturation at high algal concentrations (Riisgard et al., 2011) results in the faeces production (Eq. 16, Table 1). 219 220

## 221

#### 2.3 Microplastics accumulation sub-model

222

223 With the DEB model as a basis, a sub-model describing the microplastics (MPs) accumulation 224 by the mussel was developed, assuming that the presence of MPs in the ambient water does not 225 cause a significant adverse effect on the organisms' overall energy budget, in accordance with laboratory experiments, conducted in mussel species (Van Cauwenberghe et al., 2015: Mytilus 226 227 edulis, Santana et al., 2018: mussel Perna perna). Additionally, it was assumed that the mussel 228 filtrates MPs present in the water, without the ability of selecting between the high energetic valued 229 particles and the MPs during the filtration process (Van Cauwenberghe et al., 2015, Von Moos et 230 al., 2012, Browne et al., 2008, Digka et al., 2018a among others). The uptake of MPs from the environment is taken into account through the process of clearance/filtration rate, while the 231 232 excretion of the contaminant is derived from two processes: (i) pseudofaeces production and (ii) faeces production. The resulting MPs accumulation is influenced by external environmental factors 233 234 (MPs concentration, food availability, temperature) and internal biological processes (clearance, filtration, ingestion, growth). All these are described by the following differential equation: 235

237 
$$\frac{dC}{dt} = C_{env} \cdot \dot{C}_R - \dot{f}_{pf2} - \frac{\dot{f}_f}{p_{X1I}} \cdot C$$
(Eq. 18)

where  $C_R$  is the clearance rate for water (L h<sup>-1</sup>), containing a concentration of MPs  $C_{env}$  (particles L<sup>-1</sup>). The terms of  $\int_{pf2}$  and  $\frac{j_f}{p_{X1I}}$  represent the elimination rate of MPs through pseudofaeces and the non-dimensional rate of faeces production with respect to the ingestion rate, respectively (see Table 1, Eq. 15-16). In this context, the pseudofaeces production incorporates the rejected MPs prior to the ingestion, while the faeces production includes MPs that are rejected along with the food particles that are not assimilated by the mussel.

The accumulation of MPs in the individual is represented by the state variable C (particles individual<sup>-1</sup>) which is computed at every model time step. This has been set to one hour, in order to properly resolve the dynamics of the rapidly changing processes, such as feeding and excretion.

247 248 2.4 Environmental drivers

# Besides MPs concentration in the seawater, the DEB model is forced by sea surface temperature (SST) and food availability, defined as chlorophyll-a concentration (CHL-a). Hatzonikolakis et al. (2017) have tested the performance of the model, considering also particulate organic carbon (POC) in the mussel's diet, which, however, did not have an important impact on the model's skill against field data. Thus, only CHL-a, is considered as the available food source. For both study areas SST and CHL-a are derived from daily satellite data, a method also used by other authors (i.e. Thomas et al., 2011, Monaco & McQuaid, 2018).

In the North Sea, SST data were obtained from daily satellite images provided by Copernicus Marine Environmental Monitoring Service (CMEMS) at 0.04 degree spatial resolution and CHL-a data from the daily multi-sensor product provided by CMEMS- Globcolour database at 1 km spatial resolution (http://marine.copernicus.eu/, generated using CMEMS Products, production center ACRI-ST). The environmental forcing data (SST, CHL-a) were averaged over the study area (51.08°-51.44° N, 2.19°-3.45° E), covering the period 2007-2011 (5 years), in order to realistically simulate the wild mussel's growth harvested at late summer 2011 (Van Cauwenberghe et al., 2015).

In the North Ionian Sea, daily satellite SST data were also obtained from the CMEMS database for the Mediterranean Sea with 0.04 degree spatial resolution, while CHL-a data were derived from the merged product of many satellites (i.e. SeaWiFs, Meris, Modis, Viirs and Olci-a) provided by Globcolour web interface (http://globcolour.info) at a daily temporal resolution and 1 km spatial resolution. The forcing data were averaged over the study area (N 39.49°-39.65°, E 20.09°-20.23°) covering the period 2014-2015 (2 years), when the cultured mussel is ready for the market. The satellite derived CHL-a data were estimated based on the OC5 algorithm of Gohin et

270 al. (2002) in both study areas, which is regarded as suitable for coastal waters. Satellite data have 271 facilitated large scale ecological studies by providing maps of phytoplankton functional types and sea surface temperature (Raitsos et al., 2005, 2008, 2012, 2014, Palacz et al., 2013). The daily 272 273 environmental forcing data are shown in Fig. 1 and Fig. 2 for the North Sea and the N. Ionian Sea, 274 respectively. The two coastal environments present some important differences regarding both 275 CHL-a and SST. Specifically, in the N. Ionian Sea, CHL-a is relatively low (annual mean ~ 0.88 mg chl-a m<sup>-3</sup>) and peaks during winter (maximum ~2.64 mg chl-a m<sup>-3</sup> at December 2014), while in the 276 North Sea CHL-a is about four times higher (annual mean 4.25 mg chl-a m<sup>-3</sup>), peaking in April 277 every year (maximum range 29.44-33.38 mg chl-a m<sup>-3</sup>), as soon as light availability reaches a 278 279 critical level (Van Beusekom et al., 2009). The higher productivity in the North Sea is related with 280 the nutrient inputs from the English Channel, the North Atlantic and particularly the river discharge 281 of nutrient-rich waters along the Belgian-French-Dutch coastline, that peaks during winter period (Van Beusekom et al., 2009). The sea surface temperature peaks during August in both areas (Fig. 1 282 and Fig. 2), but is significantly higher in the N. Ionian Sea (maximum 28.8°C), as compared to the 283 284 North Sea (maximum 18-19.3°C).

The environmental concentration of MPs,  $C_{env}$  (particles L<sup>-1</sup>) was obtained also at a daily time 285 step as randomly generated values of the Gaussian distribution that is determined by the mean value 286 and standard deviation of the observed field data (0.4  $\pm$  0.3 particles L<sup>-1</sup>, North Sea, Van 287 Cauwenberghe et al., 2015, 0.0012  $\pm$  0.024 particles L<sup>-1</sup>, N. Ionian Sea, Digka et al., 2018a). 288 Considering that these values originate from surface waters and that mussels live in the near surface 289 layer (0-5 m),  $C_{env}$  is estimated as a mean value of the upper layer with the methods described by 290 291 Kooi et al. (2016), who studied the vertical distribution of MPs, considering an exponential 292 decrease with depth. Specifically, in the N. Ionian Sea, mussels were collected from a depth up to 3 293 m (Digka et al., 2018a), while in the North Sea (Van Cauwenberghe et al., 2015), there is no 294 information and thus a maximum depth of 5 m is adopted.

295 In the North Sea simulation, the effect of tides is taken into account by considering that the 296 mussel originated from the intertidal zone, is submerged 12 hours during the day (Van 297 Cauwenberghe et al., 2015). In the N. Ionian Sea simulation, tides are not considered, given the 298 very small tide amplitude (few centimeters) in the Mediterranean (i.e. Sara et al., 2011; Hatzonikolakis et al., 2017) and thus the cultured mussel is assumed permanently submerged. In 299 300 situ hourly tide data (2007-2011) from the coastal zone of the region (Dunkerque station N 301 51.04820°, Е 2.36650°) obtained from Coriolis and Copernicus data provider 302 (http://marine.copernicus.eu, http://www.coriolis.eu.org), showed that mussels experience 303 alternating periods of aerial exposure and submergence at approximately every 6 hours (2 high and 304 2 low tides). During aerial exposure the model suspends the feeding processes (Sara et al., 2011)

305 and simulates metabolic depression (Monaco & McQuaid, 2018) where, the Arrhenius thermal 306 sensitivity equation (Eq. 9) is corrected by a metabolic depression constant ( $M_d = 0.15$ ), a value 307 representative for *M. galloprovincialis* and here applied also for *M. edulis*. In the present study, the 308 mussel's body temperature change during low tide is ignored, inducing a model error. The mussel's 309 body temperature (i.e. surrounding water temperature for submerged mussels) during air exposure depends on many factors, such as solar radiation, air's temperature, wind speed and wave height, 310 according to studies investigating the temperature effect on intertidal mussels (Kearney et al., 2010, 311 Sara et al., 2011). However, the present study aims to primarily examine the MPs accumulation and 312 313 thus the intertidal mussel's body temperature was not thoroughly examined. Nonetheless, the time 314 that the mussel is able to filter, ingest and excrete the suspended matter (i.e. food and MPs particles) and the effect on the mussel's growth through the modified relation of k(T) are included, since the 315 316 assimilation process occurs whether the mussel is submerged or not (Kearney et al., 2010).

- 317 2.5 Parameter values
- 318

- 319 Most of the DEB model parameters were obtained from Van der Veer et al. (2006) and are 320 referred to the blue mussel *Mytilus edulis* in the northeast Atlantic (see Table 3 for the exceptions). 321 This assumption has also been adopted in previous studies which showed that this parameter set for 322 M. edulis applies also for M. galloprovincialis (i.e. Casas and Bacher, 2006, Hatzonikolakis et al., 2017). The half saturation coefficient  $X_k$  represents the density of food at which the food uptake rate 323 324 reaches half of its maximum value and should be treated as a site – specific parameter (Troost et al., 325 2010, Pouvreau et al., 2006). In order to estimate the value of  $X_k$ , a different approach was followed 326 for each study area.
- 327 For the North Sea simulation,  $X_k$  was tuned so that the simulated individual has the recorded 328 size at the corresponding estimated age (Van Cauwenberghe et al., 2015) growing with the 329 representative growth rates of wild M. edulis at the region (Saraiva et al., 2012, Sukhotin et al., 330 2007). For the N. Ionian Sea simulation, an alternative method was adopted, aiming to generalize 331 the DEB model to overcome the problem of site-specific parameterization. The DEB model was 332 tuned against literature field data for cultured mussels originated from different areas in the 333 Mediterranean and Black Seas, where the average CHL-a concentration ranged between 1.0 and 5.0 mg chl-a m<sup>-3</sup>, and one  $X_k$  value was found for each area. The four areas used, their characteristics 334 335 and the corresponding value of  $X_k$  adopted, are shown in Table 4. These values of  $X_k$  are related to 336 the prevailing CHL-a concentration of each area ([CHL-a]) through three different functions: linear: f(x) = a \* [CHL - a] + b exponential:  $f(x) = a * \exp(b * [CHL - a])$  and power: f(x) = a + exp(b + [CHL - a])337  $a * [CHL - a]^{b} + c$ . The curve fitting app of Matlab (Matlab R2015a) was used for the 338

339 determination of a, b and c of each function taking into account the 95% confidence level. The 340 score of each function regarding the somatic/mussel growth simulation in all four regions is tested 341 through target diagrams (Jolliff et al., 2009) by computing the bias and unbiased root-mean-square-342 deviation (RMSD) between field and simulated data of all 4 regions and the function with the best 343 score is adopted. A similar approach was followed by Alunno-Bruscia et al. (2011) for the oyster Crassostrea gigas in six Atlantic ecosystems who expressed the  $X_k$  as a linear function of food 344 345 density (e.g. phytoplankton). Unfortunately, the approach described for the N. Ionian Sea simulation could not be applied in the North Sea, as the limited amount of growth data from the 346 347 literature for wild *M. edulis* in similar environments did not permit a statistically significant fit of a 348 similar function  $(X_k = f(chl - a))$ .

- 349
- 350

#### 2.6 Simulation of reproduction-Initialization of the model

351

352 The reproductive buffer (R) is assumed to be completely emptied at spawning (R = 0) 353 (Sprung, 1983, Van Haren et al., 1994). In order to simulate mussel's spawning, the gonado-somatic index (GSI) defined as gonad dry mass over total dry flesh mass was computed at every model's 354 355 time step (Eq. 17 Table 1; the water content of the fresh tissue mass was assumed 80% according to Thomas et al. (2011)). Spawning was induced by a critical value of GSI (GSI<sub>th</sub>, Table 3) and a 356 357 minimum temperature threshold (T<sub>th</sub>) at each study area, obtained from the literature. In the North Sea implementation, T<sub>th</sub> was set at 9.6 °C (Saraiva et al., 2012), while in the N. Ionian Sea, at 15 °C 358 359 (Honkoop and Van der Meer, 1998). This kind of formulation for the spawning event in bivalves 360 has been used in previous studies (i.e. Pouvreau et al., 2006, Troost et al., 2010, Thomas et al., 2011, Monaco & McQuaid, 2018). The simulated abrupt losses of the mussel's tissue mass 361 362 correspond to spawning events and the model's prediction was compared with the available 363 literature data regarding the spawning period in each study area. Theodorou et al. (2011) demonstrated that the spawning events occur during winter for M. galloprovincialis in the mussel 364 365 farms of Greece, while in the North Sea the spawning period for *M. edulis* is extended from the end of April until the end of June (Sprung, 1983, Cardoso et al., 2007). 366

In both areas, the model was initialized so that the simulated individual is in the juvenile phase ( $V < V_p$ ; Table 3) and the reproductive buffer can be considered to be empty (R = 0) (Thomas et al., 2011). As stated by Jacobs et al. (2015) amongst others, juvenile mussels (*M. edulis*) range between 1.5-25 mm in size. Specifically, in the North Sea the settlement of mussel larvae (*M. edulis*) takes place in June and the juveniles grow to a maximum size of 25 mm within 4 months (Jacobs et al., 2014). In the N. Ionian Sea, the operating mussel farms follow the life cycle of *M*.

373 galloprovincialis, starting the operational cycle each year by dropping seed collectors from late 374 November until March and the juvenile mussels grow up to 6-6.5cm after approximately one year 375 according to the information obtained from the local farms in the region and Theodorou et al. 376 (2011). The initial fresh tissue mass was distributed between the structural volume (V) and reserves 377 energy (E). Energy allocated to those two compartments was firstly constrained by the initial length 378 (L) and then energy allocated to V was in Eq.10 (Table 1). The initial value of E was set so that the 379 simulated individual has an initial weight that corresponds to the juvenile phase ( $V < V_p$ ) (Table 5). 380 Finally, for both model implementations, the initial accumulation of MPs in the mussel's tissue (C)381 was set to zero.

382

#### 383 2.7 Simulation Runs

384 The DEB-accumulation model simulates at an hourly basis the growth and MPs accumulation 385 of the wild mussel from the North Sea and the cultured mussel from the N. Ionian Sea. Initially, a 386 model run is performed at each study area during the periods July 2007 to August 2011 (4 years) for the North Sea simulation and late November 2014 to January 2016 (~ 1 year) for the N. Ionian Sea 387 simulation. Additionally, the inverse simulations were performed in order to evaluate the depuration 388 389 phase of both cultured and wild mussel, by setting the environmental MPs concentration equal to 390 zero ( $C_{env}=0$ ), after a period of 1 year simulation at the N. Ionian Sea, when the cultured mussel has 391 the appropriate size for market, and after 4 years at the North Sea, when literature field data are 392 available (Van Cauwenberghe et al., 2015). In this simulation, the mussel's gut clearance is achieved by the excretion of MPs through faeces (3<sup>rd</sup> term of Eq. 18), and thus it is necessary to 393 maintain the existence of food in the mussel's environment in order to ensure that the feeding-394 395 excretion processes will occur.

Furthermore, to examine the model's uncertainty related to the environmental MPs concentration, a series of 15 and 13 simulations were performed in the North Sea and N. Ionian Sea respectively, adopting different constant values of  $C_{env}$  within the observed range of each area. Finally, the effect of the environmental forcing data and some model's parameters on the resulting MPs accumulation by both mussels is explored through sensitivity experiments. These were used to derive a new function that predicts the level of MPs pollution in the environment.

402

#### 403 **2.8 Sensitivity tests and Regression analysis**

404 The effect of the environmental data (CHL-a, temperature,  $C_{env}$ ) and two parameters 405 representative of mussel's growth  $(X_k, Y_k)$  on the MPs accumulation by the mussel for each study area was examined through sensitivity experiments with the DEB-accumulation model. Each 406 407 variable (CHL-a, T,  $C_{env}$ ) and parameter ( $X_k$ ,  $Y_k$ ) was perturbed by  $\pm 10\%$  and the results of each run were analyzed using the sensitivity index (SI), which calculates the percentage change of the 408 mussel's MPs accumulation  $SI = \frac{1}{n} \sum_{t=1}^{n} \frac{|C_t^1 - C_t^0|}{C_t^0} \cdot 100$  (%), where *n* is the simulated time steps,  $C_t^0$ 409 is the MPs accumulation predicted with the standard simulation at time t and  $C_t^1$  is the MPs 410 411 accumulation with a perturbed variable/parameter at time t; for details see Bacher and Gangnery, (2006). In order to also examine the effect of tides, in the North Sea implementation, the sensitivity 412 413 experiments were conducted twice: the first time assuming that the mussel is permanently submerged and the second time assuming that the mussel is periodically exposed to the air. 414

Preliminary sensitivity experiments showed that the MPs accumulation is highly depended on the prevailing conditions regarding the CHL-a, temperature and  $C_{env}$  and the mussel's growth that is regulated by the half saturation coefficient ( $X_k$ ). Therefore an attempt was made using the model's output to describe the MPs accumulation as a function of these variables through a custom regression model:

420 
$$y = b_1 * W + b_2 * exp\left(\frac{1}{T}\right) + b_3 * \frac{1}{[CHL-a]} + b_4 * C_{env}$$
 (Eq. 19)

where y (particles/individual) is the response variable and represent the predicted MPs accumulation by the mussel; W (g) the mussel's fresh tissue mass, T (K) the sea surface temperature, CHL-a and  $C_{env}$  are the concentrations of chlorophyll-a and MPs in the water respectively, which are the predictor variables. The values of coefficients  $b_1$ ,  $b_2$ ,  $b_3$ , and  $b_4$  are calculated using the nonlinear regression function (nlinfit, Matlab R2015a) which attempts to find values of the parameters b that minimize the least squared differences between the model's MPs accumulation output C and the predictions of the regression model y = f(W, T, [chl a], Cenv, b).

The ultimate aim of this analysis, once coefficients are determined, is to use equation 19 to obtain the environmental MPs concentration:

430 
$$C_{env=1/b_4} * \left(C - b_1 * W - b_2 * exp\left(\frac{1}{T}\right) - b_3 * \frac{1}{[CHL-a]}\right)$$
 (Eq. 431 20)

which could be a very useful tool to predict the MPs concentration in the environment, when allinvolved variables are known (mussel size, accumulated MPs, temperature and CHL-a), using the

434 mussel as a potential bioindicator (Li et al., 2016, Li et al., 2019). The score of this custom model 435 was tested by applying Eq. 20 in our study areas and 6 more areas around the U.K., where 436 information of mussel's wet weight and both mussels' and environment's MPs load is available (Li 437 et al., 2018). CHL-a and temperature, which were not included in Li et al. (2018), were obtained 438 from daily satellite images (same source as in the North Sea, see 2.4 section), covering the period 439 that the mussels were harvested (Li et al., 2018).

440

### 441 **3. Results**

442

#### 443 **3.1** Growth simulations

444

445 The growth simulations of *M. edulis* and *M. galloprovincialis* for the North Sea and the N. Ionian Sea are shown in Fig. 4 and Fig. 5 respectively. In the North Sea implementation,  $X_k$  was 446 tuned to a constant value:  $X_k=8$  mg chl-a m<sup>-3</sup>. The fitted value was slightly higher, as compared to 447 the one ( $X_k$ =3.88 µg chl-a l<sup>-1</sup>) used by Casas and Bacher (2006) in productive areas of the French 448 Mediterranean shoreline (average CHL-a concentration 1.45 µg chl-a l<sup>-1</sup> maximum peak at 20 µg 449 chl-a l<sup>-1</sup>), given the even higher productivity in the North Sea (average CHL-a concentration 4.25 450  $\mu$ g chl-a l<sup>-1</sup>; maximum peak at ~33.40  $\mu$ g chl-a l<sup>-1</sup>). The high value of  $X_k$  could also be explained by 451 452 the presence of silt and other inedible particles (i.e. MPs) which result to lower quality food in the mussel's diet compared with a "clean" site (Kooijman, 2006, Ren, 2009). Furthermore, it has been 453 reported that wild mussels grow considerably slower than farmed mussels (~1.7 times) (Sukhotin 454 and Kulakowski, 1992) and thus, a higher value of  $X_k$  promotes a lower mussel growth, which is the 455 456 case of the North Sea mussel. The simulated mussel shell length after 4 years, in August, is 4.35 cm and the fresh tissue mass is 1.87 gr, in agreement with Van Cauwenberghe et al. (2015) and other 457 458 studies conducted on wild mussels (Sukhotin et al., 2007, Saraiva et al., 2012, MarLIN, 2016). In particular, Saraiva et al. (2012) found that after 16 years of simulation, the wild mussel of the 459 460 Wadden Sea (North Sea) is 7 cm long, while according to Bayne and Worral (1980) a mussel with 461 shell length 4 cm corresponds to the age of 4 years, in agreement with the current study. The 462 simulated growth presents a strong seasonal pattern, being higher during spring and summer season, as compared to autumn and winter, which is consistent with the seasonal cycle of temperature and 463 464 CHL-a concentration, for a typical year in the region (Fig. 1). The increase of food availability and 465 temperature during spring (April) results in high mussel growth for a 4-month period, while the 466 decrease of CHL-a from summer until the end of the year, in conjunction with the temperature

467 decrease in autumn, result in a lower mussel growth. Spawning events occurred between the end of April and beginning of May (30 April-2 May) each year, are responsible for the sharp decline in 468 mussel's fresh tissue mass, shown in Fig. 4 (Handa et al., 2011; Zaldivar, 2008) and in agreement 469 470 with the literature (Sprung, 1983, Cardoso et al., 2007, Saraiva et al., 2012). The predicted weight 471 loss due to spawning was around 7% at the first year of simulation, while the second, third and 472 fourth year the percentage of weight loss increased gradually to 8.3%, 12.6% and 14.4% 473 respectively. Bayne and Worral (1980) demonstrated that the weight losses on spawning for 474 individuals of 1 g weight vary between 2.1% and 39.8%, presenting a weight-specific increase with 475 size.

476 In the N. Ionian Sea implementation,  $X_k$  is applied as a function of CHL-a concentration through the method described in section 2.5. The target diagram showing the performance of each 477 tested function (linear: f(x) = a \* [CHL - a] + b, where a = 0.959 and b = -1.420; exponential: 478  $f(x) = a * \exp(b * [CHL - a])$  where a = 0.2 and b = 0.567; power:  $f(x) = a * [CHL - a]^{b} + a^{2}$ 479 480 c where a = 0.01, b = 3.529 and c = 0.480) is shown in figure 3. The linear and power function of  $X_k$  present a good skill, with the power function leading to the most successful simulation of the 481 cultured mussel's growth in all four areas (diagram marks for mussel length and fresh tissue mass 482 are closer to the target's center). The power function applied in the N. Ionian Sea, resulted in 483 484 mussel's shell length 5.8 cm and fresh tissue mass 5.92 gr after one year simulation, in agreement 485 with Theodorou et al. (2011). The spawning event occurred at the beginning of December 486 (Theodorou et al., 2011) and was illustrated by 12.6% tissue mass decline.

487

488

### 3.2 Microplastics accumulation and depuration phase

489

490 The hourly simulated MPs accumulation by the mussel in the North Sea and N. Ionian Sea are 491 shown in Fig. 6 and Fig. 7 respectively. In the North Sea, a 4-year-old wild mussel (L=4.35 cm, W=1.87 g) contains 0.64 particles individual<sup>-1</sup> in August within the range value found by Van 492 Cauwenberghe et al. (2015)  $(0.4 \pm 0.3 \text{ particles individual}^{-1})$ . It is worth noting that Van 493 494 Cauwenberghe et al. (2015) allowed a 24 h clearance period, before analyzing mussels' tissue for 495 MPs, possibly resulting in slightly lower MPs accumulation than the model's prediction. In the N. 496 Ionian Sea, the simulated MPs accumulation by the cultured mussel with L =4.88 cm and W =3.43 g was 0.91 particles individual<sup>-1</sup> in July, in agreement with field observations obtained from Digka 497 et al. (2018a)  $(0.9 \pm 0.2 \text{ particles individual}^{-1})$ . In both regions, the model computed MPs 498 accumulation, assuming that the mussel treats MPs as silt particles (i.e. inedible particles) and is in 499 500 agreement with the available field data. This suggests that mussels probably present a common

behavior against all inedible particles. In model's results, based on the uptake and excretion rates of MPs by the mussels in both study areas, the majority of MPs are rejected through pseudofaeces and fewer through faeces production (not shown). This is in agreement with Woods et al. (2018) who found that most microplastic fibers (71%) were quickly rejected as pseudofaeces and < 1% excreted in faeces.

The small-scale fluctuations of MPs in the mussel (wild and cultivated) reflect the adopted random variability of the environmental MPs concentration  $C_{env}$  and the daily environmental forcing (CHL-a, temperature). The large-scale (seasonal) variability follows mainly the variability of the clearance rate. The seasonal variability of the CHL-a concentration and temperature greatly determines the variability of the clearance rate and hence the variability of MPs in the individual. Moreover, the model predicts that mussel's energy needs are increased as it grows and therefore the clearance rate is increased, resulting in higher MPs accumulation.

The simulated time needed to clean the mussel's gut from the MPs load for both areas is 513 shown in Fig. 8. In both areas, the cleaning follows an exponential decay, in agreement with Woods 514 515 et al. (2018). In particular, the model predicts a 90% mussel's cleaning after 330 hours (~14 days) 516 and 63 hours (~3 days) for the N. Ionian Sea and North Sea respectively. The cleaning process is 517 more rapid in the North Sea simulation, which can be attributed to the higher CHL-a concentration found in this area, leading to increased production of faeces by the mussel and hence faster 518 519 excretion of the accumulated MPs. In the N. Ionian Sea, on the other hand, the rate of the mussel's 520 cleaning is slower, due to the limited food availability.

521

#### 522 **3.3** Model's uncertainty regarding the environmental microplastics concentration

523

The MPs concentration in the environment presents a strong variability in both temporal and 524 525 spatial scales. To examine the model's uncertainty related to the environmental MPs concentration 526  $(C_{env})$ , a series of 15 and 13 simulations were performed in the North Sea and N. Ionian Sea respectively, adopting different values of  $C_{env}$  within the observed range of each area. In the North 527 Sea, the adopted  $C_{env}$  ranged between 0.1 and 0.8 particles L<sup>-1</sup> with a step of 0.05 (15 runs), while in 528 the N. Ionian Sea  $C_{env}$  ranged between 0.0012 and 0.0252 particles L<sup>-1</sup> with a step of 0.002 (13 529 runs). The mean seasonal values and standard deviation of the 15 simulations in the North Sea and 530 531 the mean monthly values and standard deviation of the 13 simulations in the N. Ionian Sea were 532 computed and plotted in Fig. 9 and Fig. 10, respectively. Each error bar represents the uncertainty 533 of the simulated accumulation at the specific time, related to the environmental MPs concentration.

535 In both case studies, the uncertainty of the model appears to increase as the MPs accumulation is increased. As the mussel grows in the North Sea, the mean value and standard deviation of MPs 536 537 accumulation is increased during the same season every year, illustrating the effect of the mussel's 538 weight. Moreover, the seasonal variability of the MPs accumulation should be caused by the seasonality of CHL-a concentration. This is apparent during each year's spring: when CHL-a 539 concentration peaks at its maximum value (~30 mg m<sup>-3</sup>; see Fig. 1), the filtration rate is decreased 540 541 (Riisgard et al., 2003, 2011), leading to lower MPs accumulation by the mussel and thus lower 542 model's uncertainty. In the N. Ionian Sea, the effect of the mussel's weight is more apparent in the 543 early months (~ 6 months), resulting on higher MPs accumulation and model uncertainty as the 544 mussel grows. Afterwards, the seasonality of both CHL-a concentration and temperature plays the major role. During summer, when the CHL-a concentration is progressively decreased, reaching 545 minimum values (~0.7 mg /m<sup>3</sup>) and temperature is increased (>20° C), the filtration rate is 546 significantly decreased or stopped, resulting in lower MPs accumulation and lower model's 547 548 uncertainty. This is in line with studies reporting that the mussel suspends the filtering activity and 549 thus closes its valves until better conditions occur (Pascoe et al., 2009, Rissgard et al., 2011). 550 Overall, the available field data lie within the model's uncertainty for both study areas.

Moreover, to evaluate the scenario adopted with the set-up of the previous experiments (random  $C_{env}$  at a daily time step) 3 additional model runs are performed in each study area, adopting each time different stochastic sequences of daily random  $C_{env}$  values within the observed range, which is considered to reflect the high spatial and temporal variability of the environmental MPs concentration. The mean value and standard deviation of these "stochastic" runs lie most of the time within the standard deviation of the overall model's uncertainty in both case study areas (Fig. 9 and Fig. 10).

558

#### 559 **3.4 Sensitivity and Regression analysis results**

560

The results of the sensitivity experiments regarding the MPs accumulation by the mussels are 561 562 shown in Fig. 11 and 12 for the North Sea and N. Ionian Sea respectively. The comparison between 563 the intertidal and subtidal mussel of the North Sea revealed that both +10% and -10% perturbation of CHL-a and  $X_k$  have a slightly lower effect on the MPs accumulation by the intertidal mussel 564 which is probably attributed to the intermittent feeding periods experienced by the individual due to 565 566 the tide effect. As far as the temperature effect, both +10% and -10% perturbed value led to higher 567 sensitivity on the MPs accumulation by the intertidal mussel, due to the adopted modified 568 temperature relation during low tide. Especially, if the mussel's body temperature change during air

exposure would be considered, the perturbed temperature will probably affect even more the MPs accumulation on the intertidal than the subtidal mussel. The effect of the  $C_{env}$  is slightly higher and lower on the MPs accumulation by the intertidal mussel when perturbed +10% and -10% respectively, however the difference of the sensitivity index (%) between the two mussels (intertidal vs. subtidal) is small, indicating that the environmental MPs concentration affects similarly both mussels, regardless the continuous or intermittent feeding-excretion process.

The comparison between the mussel sensitivity indexes in the N. Ionian and the North Sea 575 576 (in conditions of submergence) study areas reveals some important differences. Generally, most of the perturbed (either +10% or -10%) variables and parameters (i.e. CHL-a, temperature,  $X_k$ ) present 577 578 higher sensitivity on the MPs accumulation by the mussel from the N. Ionian Sea. This is attributed 579 to the prevailing environmental conditions and specifically the lower food availability (CHL-a) and 580 the higher temperature range in the N. Ionian Sea compared to the North Sea, which greatly determine the feeding processes, the mussel's growth and hence the MPs accumulation. The 581 582 perturbed  $C_{env}$  in both study areas appears to affect similarly the MPs accumulation on both mussels 583  $(\neg 10\%)$ , with the small difference probably attributed to the higher abundance of seawater's MPs 584 present in the North Sea compared to the N. Ionian Sea. Finally, the half saturation coefficient for 585 the inorganic particles  $(Y_k)$  has no effect on the MPs accumulation of both North Sea and N. Ionian 586 Sea mussels, indicating that the amount of inedible particles (i.e. MPs) is relatively low in both areas and thus the  $Y_k$  does not affect the way that the organic particles are being ingested 587 588 (Kooijman, 2006). According to Ren (2009), when the inorganic matter is low, the K(y) (Eq. 5; Table 1) is approximately equal to  $X_k$  and then  $Y_k$  is the least sensitive parameter for the ingestion 589 590 rate and thus growth.

591 The DEB-accumulation model output was used to determine the coefficients in Eq. 19 by the nonlinear regression analysis:  $b_{1}=0.1909 (\pm 0.0006), b_{2}=0.0412 (\pm 0.0019), b_{3}=0.1315 (\pm 0.00)$ 592 593 and b4=1.1060 ( $\pm$  0.0253). The confidence intervals for the estimated coefficients ( $b_1$ ,  $b_2$ ,  $b_3$ ,  $b_4$ ) are 594 small enough which indicates an accurate estimation of them and the mean squared error of the 595 regression model is small enough (MSE=0.0523). Subsequently, as shown in Figure 13, Equation 596 20 may be used to predict the MPs concentration of the environment where mussels live, being in 597 most cases within the standard deviation of the field data. However, this is just a rough demonstration of the method and should be implemented in more environments in order to be 598 599 further validated.

600

### 602 **4. Discussion**

603

604 A DEB-accumulation model was developed and validated with the only available data from 605 the North Sea and the N. Ionian Sea, to study the MPs accumulation by wild M. edulis and cultured 606 M. galloprovincialis, as they grow in different environments. Although the study is limited by scarce validation data, it is notable that the accumulation submodel's parameters are extracted from 607 608 literature (Table 3) illustrating that mussels adopt a common defensive mechanism against inedible 609 particles (i.e. silt, MPs). Thus, the theoretical background constructed by Saraiva et al., (2011a) 610 (based on Kooijman, 2010) regarding the feeding and excretion processes of the mussel remains unspoiled. Through the strong theoretical background of DEB theory, this study highlights that the 611 612 accumulation of MPs by the mussel is highly depended on the prevailing environmental conditions 613 which control the amount of MPs that the mussel filtrates and excretes.

614 Beginning with the generalization of the DEB model regarding the site-specific parameter  $X_k$  in the N. Ionian Sea simulation, the function of the half saturation  $(f(x) = a * [CHL - a]^b + c)$ 615 successfully captures the physiological responses and thus the growth rate of the cultured mussel. In 616 617 the current study, a demonstration of this method is conducted leading to a DEB growth model 618 robust enough with a sufficiently generic nature for the simulation of the mussel growth in 619 representative mussel habitats of the Mediterranean Sea, covering a range of productivity and sea 620 surface temperature. Bourles et al. (2008) suggested for oyster growth (Crassostrea gigas) that a 621 seasonally varied half saturation coefficient could improve the accuracy of the food quantifier 622 because seawater composition is closely related to the season. As more field data becomes available 623 from various environments, such an approach could result to more generic formulations for the site-624 specific parameter  $X_{k}$ , so that the model could be applied in several areas of interest, where field 625 growth data are absent and/or to simulate the potential mussel growth in the 2D space.

626 The simulation of MPs accumulation by the mussels, using the DEB-accumulation model, is in good agreement with the available field data. The MPs accumulation by the cultivated mussel 627 (fresh tissue mass 3.42 g) originated from the N. Ionian Sea with mean  $C_{env}=0.0012\pm0.024$ 628 particles L<sup>-1</sup>, is 0.91 particles individual<sup>-1</sup> and by the wild mussel (fresh tissue mass 1.87 g) from the 629 North Sea with mean  $C_{env}=0.4\pm0.3$  particles L<sup>-1</sup> is 0.64 particles individual<sup>-1</sup>. If these 630 concentrations are expressed per gram of wet tissue of mussels, the cultivated mussel contamination 631 (0.27 particles g<sup>-1</sup>w.w.) is comparable with the wild mussel (0.34 particles g<sup>-1</sup>w.w.), despite the 632 633 much lower environmental MPs concentration  $(C_{env})$  in the N. Ionian Sea than the North Sea. This 634 comparison aims to highlight the significant impact of the prevailing environmental conditions 635 (CHL-a and temperature) on the MPs accumulation by the mussels, although they originate from

636 different areas and lived different time period. The generally high abundance of CHL-a in the North 637 Sea simulation, contributes to a reduction of the filtering activity and hence of the MPs accumulation. The threshold algal concentration for reduction of the mussel's filtration rate 638 (incipient saturation) has been found to lie between 6.3 and 10.0  $\mu$ g chla L<sup>-1</sup> (Riisgard et al., 2011), 639 which is the North Sea case. Furthermore, in the N. Ionian Sea simulation, the filtration, ingestion, 640 pseudofaeces and faeces production rates are decreased during the summer season when the CHL-a 641 and temperature has downward and upward trend respectively, gradually leading to a decline of the 642 mussel's MPs accumulation. Van Cauwenberghe and Janssen (2014) found that cultivated M. edulis 643 from the North Sea contained on average  $0.36 \pm 0.07$  particles g<sup>-1</sup>w.w., a similar value with that 644 found in the present study for the wild mussel of the North Sea (0.34 particles g<sup>-1</sup>w.w.). This 645 probably highlights the small contribution of mussel farms as a source of MPs pollution (Santana et 646 647 al., 2018). Moreover, the intertidal wild mussel (present study) is assumed to filter and excrete MPs half of the time in comparison with the submerged cultured mussel in the North Sea, resulting 648 649 though in similar accumulation level. The model also predicts the time needed for the 90% gut 650 clearance of both cultured (N. Ionian Sea) and wild (North Sea) mussel to be almost 330 hours and 651 63 hours (equivalent to 14 and 3 days) respectively, when MPs contamination is removed from their 652 habitat. This is in line with a series of studies which demonstrated that the depuration time varies between 6-72 hours and can last up to 40 days depending on several factors such as species, 653 environmental conditions (Bayne et al., 1987), size and type of MPs (Browne et al., 2008, Ward and 654 655 Kach, 2009, Woods et al., 2018, Birnstiel et al., 2019).

656 The strong dependence of food (CHL-a), temperature and seawater's MPs concentration on 657 the MPs accumulation by the mussel, regarding its wet weight, is demonstrated through sensitivity 658 experiments that were used to derive a rather simple nonlinear regression model (Eq. 19). The comparison of the regression model's with the DEB model's output resulted in a quite accurate 659 660 estimation of the coefficients, which in turn sparked the idea of a 'new' relationship (Eq. 20) that 661 could potentially predict the MPs concentration in the environment when certain conditions are known (CHL-a, T, C<sub>env</sub>, W). The latter equation was applied in 8 areas in total (2 from the present 662 study areas and 6 from Li et al. (2018), with relatively good results since the predicted value is 663 664 within the observed range of field data in most regions, making the mussel a potential bioindicator. Mussels have been previously proposed as bioindicators for marine microplastic pollution (<1 mm), 665 although the efficient gut clearance and selective feeding behavior limit their quantitative ability 666 (Lusher et al., 2017, Brate et al., 2018, Beyer et al., 2017, Fossi et al., 2018, Li et al., 2019).The 667 very recent study by Ward et al. (2019) demonstrated that bivalves are poor bioindicators of MPs 668 pollution due to the particle selection during feeding and excretion processes that is based on the 669 physical characteristics of the MPs. Considering that the MPs accumulation is site-depended and 670

671 that sampling of mussels is usually easier than seawater (Karlsson et al., 2017, Brate et al., 2018), 672 models like the one described in Eq. 20 that besides the MPs accumulation take into account 673 characteristics of the environment, which are crucial for the way that mussels accumulate MPs, 674 possibly could be used at global level and allow comparisons between various environments. 675 However, the method described should be validated in more environments with more frequent field 676 data to be able to provide secure results.

Despite the scarce validation data, in this study there are some other limitations. First of all, 677 678 the data regarding the concentration of MPs in the mussels' environment is also scarce; since MPs 679 is a relatively recent subject of study, the existing knowledge of the spatial and temporal 680 distribution is still quite limited (Law and Thompson, 2014, Browne, 2015, Anderson et al., 2016, de Sa et al., 2018, Smith et al., 2018, Troost et al., 2018). To overcome the lack of environmental 681 682 MPs time series, a function of randomly generated values within the observed range of each area 683 was applied and its uncertainty was examined through an ensemble forecasting. Specifically, the model's uncertainty due to the environmental MPs concentration  $(C_{env})$  was tested by performing a 684 685 series of model runs forced by an envelope of representative values of  $C_{env}$  and the results (section 686 3.3) show that the adopted stochastic scenario simulates realistically the MPs accumulation by the 687 mussels and in agreement with the available field data. The approach used is assumed to be close to 688 reality since it has been reported that MPs quantification in the water is rather a complicated procedure due to the influence of many factors such as tides, wind, wave action, ocean currents, 689 690 river inputs and hydrodynamic features resulting to high spatially and temporally variability of MPs distribution even in very small scales (Messinetti et al., 2018, Goldstein et al., 2013). In a future 691 692 work the DEB-accumulation model could be coupled with a high-resolution MPs distribution model 693 (Kalaroni et al., 2019) to overcome this limitation. Moreover, the approach followed in calculating 694 the value of MPs concentration in the near surface layer (0-5m depth) (Kooi et al., 2016), resulted in 695 a representative value of the upper ocean layer. In depth knowledge of the MPs distribution, both 696 horizontally and vertically, is essential to understand and mitigate their impact not only on the 697 various marine compartments but also on the organisms inhabiting those (Van Sebille et al., 2015, 698 Kooi et al., 2016). For that reason, it is important to enhance the monitoring activity especially in 699 the vulnerable coastal environments, adopting integrated cross-disciplinary approaches and monitoring of biological, physical and chemical parameters which provide information on the 700 701 ecosystem function, in order to improve the assessment of emerging pollutants (i.e. MPs) and their 702 impacts on biota (objective of JERICO-RI framework).

Further, the assumption that the mussel has the same filtration rate for all particles independently of their chemical composition, size and shape, is a simplification and a contradictory theme of discussion (see Saraiva et al., 2011a for details). However, through the model, a pre-

706 ingestive particle selection by the mussel is implied based on the organic-inorganic content of the 707 suspended matter illustrating the different binding probabilities applied for algal and MPs particles 708 during the ingestion process. Through an investigation of wild mussel's faeces and pseudofaeces 709 production in laboratory conditions, Zhao et al. (2018) found that the length of MPs was significantly longer in pseudofaeces than in the digestive gland and faeces. Furthermore, Van 710 711 Cauwenberghe et al. (2015) demonstrated that mussel's faeces contained larger MPs (15-500 µm) 712 compared to the mussel's tissue (20-90 µm). Apparently, smaller sized MPs seem to be dominant 713 within the mussels in comparison with the ambient environment (Li et al., 2018, Qu et al., 2018, 714 Digka et al., 2018b), implying that the mussel is more prone to ingest and retain smaller sized MPs. 715 As an example, Digka et al. (2018b) confirmed that the smaller MPs (<1 mm) occupy the 62.3%, 716 96.9% and 100% in seawater, sediments and mussels from the N. Ionian Sea respectively. In a 717 future work this selection pattern regarding size, could be simulated by suitable preference weights among different MPs sizes. This will improve the knowledge of the feeding and excretion 718 719 mechanisms used by the mussels against MPs pollution and the assessment of the ecological 720 footprint (Rist et al., 2019).

721 Moreover, the assumption that the contamination by MPs does not affect the energy budget 722 in terms of growth might also be a simplification as this is a subject currently under investigation. 723 Van Cauwenberghe et al. (2015) found that although mussels M. edulis exposed to MPs increased 724 their energy consumption, the energy reserves was not affected compared to the control organisms, 725 implying that mussels are able to adopt a defensive mechanism against the suspended inorganic particles (i.e. MPs) (Ward and Shumway, 2004). Furthermore, MPs exposure showed no significant 726 727 effect on mussel's Perna perna energy budget, despite its long duration and relatively realistic 728 intensity, concluding to the assumption of mussel's acclimation to maintain its health (Santana et 729 al., 2018). On the contrary, other authors who mainly intended to predict future effects, suggested a 730 significant energy shift from reproduction to structural growth and elevated maintenance costs, 731 probably attributed to the reduced energy intake, when the organisms (i.e. oyster Crassostrea gigas) 732 were contaminated with high and unrealistic concentration of MPs (Sussarellu et al., 2016). 733 Moreover, Gardon et al. (2018) showed that the overall energy balance of oyster Pinctada 734 margaritifera was significantly impacted by the reduced assimilation efficiency in correlation with the exposed dose of MPs and for that reason energy had to be withdrawn from reproduction to 735 736 compensate for the energy loss. In future dedicated experiments exploring the effects on all 737 components of a DEB model should be carried out considering long-term realistic MPs exposure.

Furthermore, the tide data as considered in the present study impose model's bias, since the mussel's body temperature change when exposed to air was not taken into consideration. Assessing mussel's body temperature demand extended experiments in field conditions (Tagliarolo and

741 McQuaid, 2015, Monaco and McQuaid, 2018). A very recent study by Seuront et al. (2019) along 742 the French coast of the eastern English Channel found no significant correlation between air's and mussel's body temperature but rather positively significant correlation with the hard substrate's (i.e. 743 744 rocks) temperature. However, in the present study the tide effect on processes that are affected by 745 the thermal equation (k(T)) is considered through the metabolic depression (details in section 2.4). 746 Sara et al. (2011) following the method developed by Kearney et al. (2010), who coupled a DEB 747 model with a biophysical model, incorporated the change of mussel's body temperature during 748 emersion, using information of various climatological variables (i.e. solar radiation, air temperature, wind speed, wave height), but the temperature sensitivity on the physiological processes was 749 750 ignored. In a future study, a similar approach by coupling the present DEB-accumulation model 751 with a biophysical model could be followed and lead to a more detailed simulation of the mussel's 752 body temperature.

753 754

### 5. Conclusions

755 In a future study the model should be validated against more frequent field data regarding the MPs accumulation, with sampling of mussels among various sizes and life stages as for now it 756 757 cannot be reliable in conducting predictions within accepted precision. However, this study 758 provides a new approach in studying the accumulation of MPs by filter feeders and reveals the 759 relations between characteristics of the mussel's surrounding environment and the MPs 760 accumulation, which is presented with high seasonal fluctuations. Additionally, in a future study the DEB-accumulation model will be coupled with a coupled hydrodynamic-biochemical model 761 762 (Petihakis et al., 2002, 2012, Triantafyllou et al., 2003, Tsiaras et al., 2014, Ciavatta et al., 2019, Kalaroni et al., 2020) and a MPs distribution model (Kalaroni et al., 2019) that will provide fields of 763 764 temperature, food availability and MPs concentration respectively at the Mediterranean scale, and 765 eventually lead to an integrated representation of the MPs accumulation by mussels (Daewel et al., 2008). This fully coupled model will be downscaled to the Cretan Sea SuperSite, while the 766 767 parameterization of important biological processes will be redesigned based on the new data which 768 will be acquired in the framework of the JERICO S3 project (http://www.jerico-ri.eu). The present 769 study highlights the urgent need for adopting a multi-disciplinary monitoring activity by measuring 770 physical, biological and chemical parameters that are crucial for mapping the MPs distribution, 771 assessing the contamination level of the marine organisms and investigating the impact on the 772 health status. Overall, despite the significant limitations that were mentioned before, taken into 773 account that plastics are one of the global hot issues, this particular study could help for the design 774 of next efforts, since it provides indications on the future priority related issues.

 Table 5. Dynamic energy budget-accumulation model: initial values. L: shell length; W: fresh tissue mass; V: structural volume; E: energy reserves; R: energy allocated to reproduction; C: Microplastics accumulation

Fig. 1. Environmental data used for the forcing of the dynamic energy budget model in the North Sea simulation,
 showing temperature (top) and chlorophyll a concentration (bottom).

Fig. 2. Environmental data used for the forcing of the dynamic energy budget model in the Northern Ionian Sea simulation, showing temperature (top) and chlorophyll a concentration (bottom).

1318

1319Fig. 3. Target diagram of simulated shell length (L) and fresh mass tissue weight (W) against field data from1320Thermaikos and Maliakos Gulf (eastern Mediterranean Sea), Black Sea and Bizerte Lagoon (southwestern1321Mediterranean Sea), using the power (L1, W1), exponential (L2, W2) and linear (L3, W3) function of the half saturation1322coefficient. The model bias is indicated on the y-axis while the unbiased root-mean-square-deviation (RMSD) is1323indicated on the x-axis.

1324

1329Fig. 5. Simulated mussel shell length (L) (top) and fresh tissue mass (W) (bottom) against Northern Ionian Sea data1330(red star: mean  $\pm$  SD), using chlorophyll a (X = [CHL-a]) in the mussel diet.

1331

1328

1333Fig.6. Microplastics (MPs) accumulation by the mussel (blue line) against field data (red star: mean  $\pm$  SD), using daily1334environmental concentration of MPs ( $C_{env}$  mean value  $\pm$  SD:  $0.4 \pm 0.3$  particles  $L^{-1}$ ) in the North Sea.

1335

1336Fig. 7. Microplastics (MPs) accumulation by the mussel (blue line) against field data (red star: mean value  $\pm$  SD),1337using daily environmental concentration of MPs (Cenv mean value  $\pm$  SD: 0.0012  $\pm$  0.024 particles  $L^{-1}$ ) in the Northern1338Ionian Sea.

1339

1340

Fig. 8. Depuration phase of the cultured Mytilusgalloprovincialis (red line) and wild Mytilus edulis (black line) using
 zero environmental concentration of microplastics (C<sub>env</sub>=0) after 1 year and 4 years of simulation time at the Northern
 Ionian Sea and North Sea respectively.
