10 **Abstract.** Based on a set of climate simulations utilizing two kinds of Earth System Models (ESMs) to which observed ocean hydrographic data are assimilated with an exactly same data assimilation procedure, we have clarified that successful simulation of observed historical air–sea CO₂ flux variations in the equatorial Pacific is tightly linked with the reproducibility of physical air–sea coupled processes. When an ESM with weaker amplitude of ENSO (El Niño Southern Oscillations) than observations was used for historical simulations with the ocean data assimilation, observed equatorial
15 anticorrelated relationship between the sea surface temperature (SST) and air–sea CO₂ flux on seasonal–decadal timescales cannot be represented. The simulated CO₂ flux anomalies were upward (downward) during El Niño (La Niña) periods. The reason is that nonnegligible correction term on the governing equation of ocean temperature, which was added through the ocean data assimilation procedure, caused anomalously spurious equatorial upwelling (downwelling) during El Niño (La Niña) periods, which brought more (less) subsurface layer water rich in dissolved inorganic carbon (DIC) to the surface layer.
20 This led to upward (downward) air–sea CO₂ flux anomalies during El Niño (La Niña) periods. On the other hand, such spurious vertical transport of DIC and resultant positively-correlated SST and air–sea CO₂ flux variations were not occurring in the historical simulations where the other ESM with rather realistic ENSO representation were used because the correction term arisen from the assimilation procedure was kept small enough not to disturb an anomalous advection-diffusion balance for the equatorial ocean temperature. Thus, the reproducibility of the tropical air–sea CO₂ flux variability with data
25 assimilation can be significantly attributed to the reproducibility of ENSO in an ESM. Our results suggests that, when using data assimilation to initialize ESMs for carbon cycle predictions, the reproducibility of the internal climate variations in the model itself is of great importance.

1 Introduction

Since the industrial revolution, vast quantities of greenhouse gases (e.g., CO₂) have been released into the
30 atmosphere through human activities such as fossil fuel use and land use change. Increased atmospheric CO₂ concentration

leads to global warming, while both the oceanic and the terrestrial ecosystems absorb atmospheric CO₂ and are considered to work to relax the progress of the global warming (Sabine et al., 2004; Doney et al., 2009a, 2014; Le Quéré et al., 2009, 2010, 2016). Observation-based studies have reached consensus that significant interannual variability of the air–sea CO₂ flux (hereafter, CO₂F) exists in some specific regions such as the equatorial Pacific and high latitudes of both hemispheres (e.g., 35 Park et al., 2010; Valsala and Maksyutov, 2010; Landschützer et al., 2014; Rödenbeck et al., 2014), and the variation of CO₂F associated with El Niño–Southern Oscillation (ENSO) in the equatorial Pacific has been highlighted in many previous observation-based and simulation-based studies (Keeling and Revelle, 1985; Feely et al., 1997, 1999; Jones et al., 2001; Obata and Kitamura, 2003; McKinley et al., 2004; Patra et al., 2005). When El Niño event occurs in the equatorial Pacific, dissolved inorganic carbon (DIC) concentration in the surface layer decreases due to lesser supply of the cold DIC-rich 40 subsurface water to the surface layer than normal years because of weaker equatorial upwelling associated with weaker trade winds (Le Borgne et al., 2002; Feely et al., 2004; Doney et al., 2009a, 2009b). Correspondingly, CO₂F is anomalously downward during El Niño, and vice-versa during La Niña. Le Borgne et al. (2002) estimated that upwelling of DIC-rich subsurface water accounts for up to 70% of CO₂F variation in the equatorial Pacific, while the other 30% is attributable to the variation of wind speed and biological processes. Accordingly, to estimate and predict variations of CO₂ uptake by the 45 global ocean on timescales of several years, it would be informative to consider first the variations in the equatorial Pacific associated with ENSO.

The goal of the Paris Agreement is to restrict the rise of the global mean surface air temperature to well below 2 °C relative to the preindustrial level. If greenhouse gas emissions continue to increase at their current rate, Earth’s surface will warm by 1.5 °C within ~20 years relative to the preindustrial state as reported in the fifth assessment report of the 50 Intergovernmental Panel on Climate Change (IPCC, 2013). In this context, comprehensive understanding of the changes in the carbon cycle over previous years is essential for accurate predictions of the global carbon cycle, including natural variations, which will assist in evaluation of future CO₂ emission reductions (Kawamiya et al., 2019).

For future climate predictions, data assimilation procedures are incorporated into climate models in order to synchronize simulated climatic states in the model with observations, that is, initialization of climate models. By 55 incorporating data assimilation procedures into Earth System Models (ESMs), it will be possible to reproduce and predict variations in biogeochemical properties (Brasseur et al., 2009; Tommasi et al., 2017a, 2017b; Park et al., 2018). This includes an assessment of the predictability of CO₂F on decadal timescale for the global ocean (Li et al., 2016, 2019).

Focusing on CO₂F fluctuations associated with ENSO in the equatorial Pacific, Dong et al. (2016) analyzed the results of the Earth system models (ESMs) that participated in the Coupled Model Intercomparison Project (CMIP) Phase 5 60 (CMIP5; Taylor et al., 2012), which contributed to the Fifth Assessment Report (AR5) of the Intergovernmental Panel on Climate Change (IPCC, 2013). They showed that only some ESMs could reproduce the observed anticorrelated relationship between SST and CO₂F. This suggests that our understanding of ENSO and associated global carbon cycle variations are still insufficient. For reliable prediction of future CO₂ uptake on seasonal–decadal timescales, it is necessary to understand physical air–sea coupled process and associated carbon cycle variations in the equatorial Pacific.

65 In this study, utilizing two kinds of ESMs to which observed ocean hydrographic data are assimilated, we attempted to identify the key processes to reproduce the observed historical air–sea CO₂ flux variations in the equatorial Pacific. The remainder of this paper is organized as follows. Sect. 2 provides a brief description of the models used in this study, and the derived results are presented in Sect. 3. Finally, a short discussion and a summary are presented in Sect. 4.

70

2 Methods

2.1 Model Description

In this study, we have conducted four experiments, NEW-assim, NEW, OLD-assim, and OLD. In NEW-assim and NEW, we used the MIROC-ES2L (Hajima et al., 2020) and in OLD-assim and OLD, we used the MIROC-ESM (Watanabe, S. et al., 2011). The former is newly developed for CMIP Phase 6 (CMIP6; Eyring et al., 2016), while the latter is an official model of CMIP5. The physical core model of MIROC-ES2L is MIROC5.2, which is a minor update of MIROC5 (Watanabe, M. et al. 2010; Tatebe et al. 2018), while that of MIROC-ESM is MIROC3m (K1 model developers, 2004). The horizontal resolution of the atmospheric component of MIROC-ES2L (MIROC-ESM) has T42 spectral truncation (i.e., approximately 300 km) with 40 (80) vertical levels up to 3 hPa (0.003 hPa). The oceanic component of MIROC-ES2L has a horizontal tripolar coordinate system. In the spherical coordinate portion south of 63°N, the longitudinal grid spacing is 1°, while the meridional grid spacing varies from approximately 0.5° near the equator to 1° in mid-latitude regions. There are 62 vertical levels in a hybrid σ – z coordinate system, the lowermost of which is located at the depth of 6300 m. The oceanic component of MIROC-ESM has a horizontal bipolar coordinate system: the longitudinal grid spacing of the oceanic component is approximately 1.4°, while the latitudinal grid intervals vary gradually from 0.5° at the equator to 1.7° near both poles. There are 44 vertical levels in a hybrid σ – z coordinate system, the lowermost of which is located at the depth of 5300 m. The resolutions in MIROC-ES2L are higher than in MIROC-ESM. In particular, 31 (21) of the 62 (44) vertical layers in MIROC-ES2L (MIROC-ESM) are within the upper 500 m of depth. The increased number of vertical layers in MIROC-ES2L has been adopted in order to better represent the equatorial thermocline.

In NEW-assim and OLD-assim, we used the ESMs that incorporated the same simple scheme for ocean data assimilation, which comprised an incremental analysis update (IAU; Bloom et al., 1996; Huang et al., 2002). This technique is relatively simple compared to more elaborate ones such as ensemble Kalman filter and four-dimensional variational method, but is widely used for decadal climate predictions (e.g., Mochizuki et al., 2010; Tatebe et al., 2012). Positive aspects of IAU is relatively low computational cost, which enables decadal-to-centennial scale integration and a variety of parameter sensitivity experiments. In the IAU, during the analysis interval from $t = 0$ to $t = \tau$, the governing equation including a correction term for temperature and salinity (X) is written as follows:

$$\frac{dX}{dt} = \text{adv.} + \text{diff.} + F + \frac{\alpha}{\tau} \Delta X^a, \quad (1)$$

where adv. is the advection term, diff. is the diffusion term, F is the surface flux term, and the final term on the right-hand side is the correction term with α as a constant, and ΔX^a as the analysis increment. The analysis increment is calculated from $\Delta X^a = X^a(0) - X(0)$, where $X^a(0)$ is the analysis and $X(0)$ is the model first guess at $t = 0$; this term is held constant during the analysis interval. For $X^a(0)$ and $X(0)$, we used anomalies from monthly mean climatology during 1961–2000 in observations and models, respectively. Such a scheme often called ‘anomaly assimilation’ or ‘anomaly initialization’ is also used in many previous studies (e.g., Smith et al., 2007; Keenlyside et al., 2008; Pohlmann et al., 2009; Li et al., 2016, 2019; Sospedra-Alfonso and Boer, 2020). In addition, the IAU was applied at depths between the sea surface and 3000 m, with the values of $\tau = 1$ day and $\alpha = 0.025$ (Tatebe et al., 2012). The monthly objective analysis of ocean temperature and salinity (Ishii and Kimoto, 2009) are assimilated into the model as X^a , with linear interpolation to daily data. Because observed DIC concentration are sparse in space and time, only ocean hydrographic data are used for data assimilation in the present study. Also, any atmospheric observations/reanalysis are not applied.

Both of NEW and OLD are the exactly same as the historical simulations designated by CMIP6 and CMIP5 protocols, respectively, with three ensemble members for each which are bifurcated from arbitrary years of the corresponding preindustrial control simulations. The ocean data assimilation experiments, NEW-assim and OLD-assim, are bifurcated from NEW and OLD at the year 1946, respectively, and they are integrated up to the year 2005. Note that the data assimilation experiments are driven with the same external forcings as in the historical simulations. In the later sections, the model results in 1961–2005 are analyzed.

2.2 Estimating pCO₂ change at the sea surface

CO₂F depends on the difference in CO₂ partial pressure between the sea and the air, i.e.:

$$\text{CO}_2\text{F} = K(\text{pCO}_2 - \text{pCO}_2^{\text{air}})(1 - \gamma), \quad (2)$$

where pCO_2 ($\text{pCO}_2^{\text{air}}$) is the CO₂ partial pressure in the sea (air), γ is the fraction of sea ice, and $K = k\alpha$ is the CO₂ gas transfer coefficient, where k represents the CO₂ gas transfer velocity (Wanninkhof, 1992, 2014) and α represents the solubility of CO₂ in seawater (Weiss, 1974). The CO₂ gas transfer velocity k is a function of wind speed and the Schmidt number (Wanninkhof, 1992). This study investigated the reproducibility of the anticorrelated relationship between CO₂F and SST and therefore the direction of the flux is important. As K does not affect the direction and the flux variation due to ENSO has larger amplitude in terms of pCO_2 than $\text{pCO}_2^{\text{air}}$ (Dong et al., 2017), the direction of flux is governed by the variation in pCO_2 . Consequently, we evaluated the pCO_2 change at the sea surface in the equatorial Pacific.

Seawater pCO_2 values depend on temperature (T), salinity (S), DIC concentration, and total alkalinity (Alk); therefore, the change of pCO_2 can be expanded as follows:

$$\Delta \text{pCO}_2 = C(T) + C(S) + C(\text{DIC}) + C(\text{Alk}) + \text{Res.}, \quad (3)$$

where $C(X) = (\partial pCO_2 / \partial X) \Delta X$ ($X=T, S, DIC, Alk$) is the pCO_2 change due to the change in X ($X=T, S, DIC, Alk$), and Res., which includes second-order terms (Takahashi et al., 1993), was estimated so that the left-hand side and right-hand sides in Eq. (3) are equal in this study. In Sect. 3, we evaluate the CO_2F and pCO_2 variations in the equatorial Pacific in NEW-assim, NEW, OLD-assim, and OLD, and we calculate each term in Eq. (3) for each experiment.

2.3 Observation and reanalysis dataset

To assess CO_2F , ocean temperature, and wind speed of the model output, we used observation or reanalysis datasets. As the CO_2F dataset, we used the SOM-FFN (Landschützer et al., 2016, 2018). It is an estimate based on the ocean surface CO_2 observation data collection, SOCATv3 (Bakker et al., 2016), and provides monthly data since 1982. It shows significant interannual variation of CO_2F in some specific regions such as the equatorial Pacific and high latitudes of both hemispheres (Figure S1). In Sect. 3, we focus on the CO_2F in the Niño3 region ($5^\circ S-5^\circ N, 150^\circ W-90^\circ W$) which shows notable variation of CO_2F in the equatorial Pacific. This region is also the maximum variability region for SST (Gill, 1980). As the SST dataset, the observational COBE-SST2 (Ishii et al., 2005; Hirahara et al., 2014) was used. The JRA55 reanalysis (Kobayashi et al., 2015) was used for wind speed dataset.

3 Results

3.1 CO_2 flux and pCO_2 anomalies in Niño3 region

Horizontal maps for correlation coefficients between simulated and observed CO_2F are shown in Figure 1. The model output data were ensemble mean and linearly interpolated into the SOM-FFN grid. Note that the data were not detrended, and one-year running mean filter is applied to monthly CO_2F anomalies in 1982–2005 before calculating the correlation coefficients in accordance with the period for which the SOM-FFN dataset is available. CO_2F in NEW-assim shows a positive correlation with SOM-FFN in the equatorial Pacific region (Figure 1a) where significant interannual variations of CO_2F are found (Figure S1). On the other hand, CO_2F in OLD-assim (Figure 1c) is negatively correlated in the equatorial Pacific. The timeseries in the Niño3 region of both one-year running mean SST (hereafter, NINO3-SST) and CO_2F (hereafter, NINO3- CO_2F) anomalies simulated with NEW-assim (OLD-assim) are shown in Figure 1b (Figure 1d). Here, the data were detrended and monthly anomalies were calculated with respect to the 1971–2000 monthly mean climatology. The correlation coefficients between NINO3-SST and NINO3- CO_2F anomalies in NEW-assim, OLD-assim, and observation are -0.50 , 0.44 , and -0.75 , respectively (Table 1). The results in NEW-assim are consistent with the observations, while those in OLD-assim are not. The correlation coefficients between NINO3-SST and NINO3- CO_2F anomalies in NEW and OLD are -0.85 and -0.67 , respectively (Table 1 and Figure S2). Note that OLD could capture the

observed anticorrelated relationship between NINO3-SST and NINO3-CO2F anomalies, but OLD-assim could not
160 reproduce this relationship.

As the vertical direction of CO2F is determined mainly by pCO₂ at the sea surface (see Eq. (2)), we further
estimated each term in Eq. (3) for each model output (Figure 2). In order to evaluate C(X) in Eq. (2) (X = pCO₂, T, S, DIC,
or Alk), we estimated ΔX by averaging monthly mean X anomalies regressed on the NINO3-SST anomalies over the entire
Niño3 region, while $\partial pCO_2 / \partial X$ was estimated based on the climatological annual mean T, S, DIC, and Alk at the sea surface
165 within the Niño3 region in each experiment. In the following, we describe the anomalies during El Niño periods, while the
opposite applies during La Niña periods. In NEW-assim, NEW, and OLD, pCO₂ decreases because the effect of the decrease
in pCO₂ with decreasing DIC concentrations is larger than that of the increase in pCO₂ with warming (Figure 2). In OLD-
assim, however, the effect of the increase in pCO₂ with warming is larger than that of OLD, and the decrease in pCO₂ with
decreasing DIC concentrations is smaller than that of OLD, resulting in an increase in pCO₂. As noted in Sect. 1, previous
170 studies (Le Borgne et al., 2002; Feely et al., 2004; Doney et al., 2009a, 2009b) showed that variability in upwelling during
ENSO events dominates the equatorial Pacific CO2F variations through its regulation of DIC. In the following, we discuss
the temperature and vertical velocity changes associated with ENSO along the Equator.

3.2 DIC and vertical velocity changes

175 A cross section of the monthly ocean temperature anomalies regressed onto monthly mean NINO3-SST anomalies
along the equatorial Pacific is presented in Figure 3, together with the climatological annual mean depths of the 18, 20, and
22 °C isotherms. Here, monthly temperature anomalies were calculated with respect to the 1971–2000 monthly mean
climatology. The observational temperature anomalies as well as the climatological isotherms are derived from the monthly
objective analysis of ocean temperature (Ishii and Kimoto, 2009). Amplitudes of the positive (negative) equatorial
180 temperature anomalies in the upper (lower) layer of the eastern (western) equatorial Pacific in NEW are larger than in OLD
and are closer to observations. The intensity of ENSO defined as the standard deviation of detrended one-year running mean
NINO3-SST anomalies from 1961 to 2005 is shown in Table 2. The intensity of ENSO in NEW is estimated to be 1.17 °C
(Table 2), a bit stronger than the observation (0.80 °C). On the other hand, the intensity of ENSO in OLD is 0.43 °C, which
is about a half as large as that in observations. In addition, the climatological mean thermocline in NEW is tighter than in
185 OLD and is closer to observations. The improvement in ENSO reproducibility in NEW is attributable mainly to two updates
in the model configuration. The first is implementation of an updated plume model for cumulus convection with multiple
cloud types where lateral entrainment rate varies vertically depending on the surrounding environment (Chikira and
Sugiyama, 2010). The state-dependent lateral entrainment affects the strength of convectively-induced air–sea coupled
processes in the eastern tropical Pacific, and thus the ENSO amplitude in the model. More details are described in Watanabe
190 et al. (2010). The second is reduction of numerical diffusion by introducing highly-accurate tracer advection scheme in the
ocean and by increasing vertical resolutions (Prather, 1986). The equatorial thermocline in the climatic-mean state of the

tropical Pacific is more diffuse in OLD than in observation, which is partly arisen from numerical diffusion, especially in vertical advection (Tatebe and Hasumi, 2010), and this model bias is much alleviated in NEW. Correspondingly, so-called thermocline mode (e.g., Imada et al., 2006) becomes more effective and ENSO amplitude becomes larger in NEW. As the ENSO amplitude in NEW is larger than in OLD, the variation of the equatorial trade wind, which causes anomalous equatorial vertical velocity, is also larger in NEW.

To assess the variations of zonal wind associated with ENSO, we estimated the 10 m zonal wind anomalies over the NINO4 region (5°S–5°N, 160°E–150°W; the dotted line boxes in Figure 1a) which are regressed onto the NINO3-SST anomalies (Table 3). Niño4 region is the maximum variability region for the equatorial trade wind (Figure S3). Hereafter, the above-mentioned regression coefficient is referred to as wind feedback. The positive value of wind feedback in NEW (0.92 m s⁻¹ K⁻¹) indicates an westerly wind anomalies during El Niño, and this is consistent with that evaluated from the observational dataset, i.e., 1.02 m s⁻¹ K⁻¹. The wind feedback in OLD (0.46 m s⁻¹ K⁻¹) is about half of NEW and the observation.

Cross sections of the monthly upward water velocity and DIC concentration anomalies along the equator regressed onto NINO3-SST anomalies in NEW (OLD) are shown in Figure 4a and 4c (Figure 4b and 4d), respectively. By reproducing wind feedback that is consistent with the observation, the westerly wind anomalies during El Niño periods in NEW (Figure S3c) is comparable to that of the JRA55 reanalysis (Figure S3i), leading to weakening of upward vertical velocity of approximately 5×10^{-6} m s⁻¹ (Figure 4a). This weakening of upward vertical velocity causes decrease in surface DIC in the eastern equatorial Pacific during El Niño periods (Figure 4c). In OLD, the smaller wind feedback and associated smaller westerly wind anomalies than in the JRA55 reanalysis (Figure S3g) leads to weakening of upward vertical velocity of just 10^{-6} m s⁻¹ in the equatorial Pacific (Figure 4b). Although the ENSO signal in OLD is weaker than the observation, because of decrease in upward vertical velocity from normal years, the surface DIC concentration decreases during El Niño periods (Figure 4d). This is consistent with Dong et al. (2016), showing that OLD is able to qualitatively reproduce the negative correlation between SST and DIC concentration anomalies in the eastern equatorial Pacific (Figure S2b).

Next, we examined the correction term in temperature due to the data assimilation, i.e., temperature analysis increment, the final term on the right-hand side of Eq. (1), and the variations in vertical velocity and DIC concentration. Anomalies of monthly mean temperature analysis increments, vertical velocity, and DIC concentration along the equator regressed onto NINO3-SST anomalies are shown in Figure 5. The maximum absolute value of the equatorial temperature analysis increment in NEW-assim is found at 10–40 m depths in the eastern equatorial Pacific, shallower than the depth of the thermocline (Figure 5a). In NEW-assim, the wind feedback is 0.92 m s⁻¹ K⁻¹ (Table 3), which is of the same magnitude to that in NEW (0.92 m s⁻¹ K⁻¹), and the surface wind anomalies still shows similar pattern to that of the NEW (Figure S3a–d). The westerly wind anomalies in NEW-assim leads to weakening of upward vertical velocity along the equator during El Niño periods (Figure 5c). To assess the variation in equatorial vertical velocity associated with ENSO, we estimated the anomalies of the vertical velocity at the depth of the 20 °C isotherm (the depth of the thermocline) in the Niño3 region which are regressed onto the NINO3-SST anomalies. Hereafter, the regression coefficient is referred to as vertical velocity

feedback. The vertical velocity feedback in NEW-assim is estimated to be $-4.5 \times 10^{-7} \text{ m s}^{-1} \text{ K}^{-1}$, which is not significantly different from that in NEW ($-3.9 \times 10^{-7} \text{ m s}^{-1} \text{ K}^{-1}$) (Table 3). The negative value of vertical velocity feedback in NEW-assim indicates the weakening of upward vertical velocity at the depth of the thermocline during El Niño periods in the eastern equatorial Pacific (Figure 5c). The weakening of upward vertical velocity causes lesser supply of the DIC-rich subsurface water to the surface layer, leading to the decrease in surface DIC concentration (Figure 5e). In OLD, the temperature variations associated with ENSO at the depth of the thermocline in the eastern equatorial Pacific is smaller than observed (see Figure 3b and 3c), so that the correction term forces to raise the equatorial water temperature by $0.16 \times 10^{-6} \text{ }^{\circ}\text{C s}^{-1}$ during El Niño periods in order to realize observed temperature variations (Figure 5b). The wind feedback in OLD-assim is $0.48 \text{ m s}^{-1} \text{ K}^{-1}$ (Table 3), which is the same as in OLD, and the map of the wind speed anomalies shows a similar pattern to that of the OLD (Figure S3e–h); however, the warming due to data assimilation procedure during El Niño periods reduces density, leading to low-pressure anomalies. This results in anomalous cyclonic circulation and convergence, and thus enhancement of upward vertical velocity at the depth of the thermocline (Figure 5d). The vertical velocity feedback in OLD-assim is $4.1 \times 10^{-7} \text{ m s}^{-1} \text{ K}^{-1}$, which has an opposite sign to OLD, $-4.9 \times 10^{-7} \text{ m s}^{-1} \text{ K}^{-1}$ (Table 3). The positive value of vertical velocity feedback indicates the enhancement of upward vertical velocity at the depth of the thermocline during El Niño periods, which is inconsistent with observations. This spurious enhancement of upward vertical velocity during El Niño periods causes the increase in the surface DIC concentration (Figure 5f), leading to positive correlation between SST and CO₂F (Figure 1d), contrary to observations. We have to note here that even in the NEW-assim, the vertical velocity distribution (Figure 5c) is still different from NEW (Figure 4a) because of the temperature analysis increment. As already discussed, the intensity of ENSO in NEW is slightly stronger than observed (Table 2). In addition, the period of ENSO, which is defined as the peak of the power spectrum of one-year running mean NINO-SST, is 5.0 years in NEW, which is longer than 3.5 years of observations (see Table 2). Because the ENSO characteristics in NEW are not perfectly consistent with observations, model nature, namely responses of vertical velocity and DIC concentration in ENSO, are still distorted by the temperature analysis increment even in NEW-assim. This indicates that further model improvements are needed.

250 4 Discussion and Summary

In the present study, comparing the results of two ESMs to which observed ocean hydrographic data are assimilated, we have clarified that representation of the processes in the equatorial climate system is important to reproduce the observed anticorrelated relationship between SST and CO₂F in the equatorial Pacific. In the case where the ocean temperature and salinity observations were assimilated into an ESM with weaker amplitude of ENSO than observations, the correction term on the governing equation of the ocean temperature, which was introduced in the data assimilation procedure, caused spurious upwelling (downwelling) anomalies along the equator during El Niño (La Niña) periods, leading to more (less) supply of the DIC-rich subsurface water to the surface layer. Due to the resultant increase (decrease) of the surface

DIC concentration, the upward (downward) CO₂F anomalies during El Niño (La Niña) periods was induced, which was inconsistent with observation. In the case where the ocean temperature and salinity observations were assimilated into the other ESM with rather realistic ENSO representation, anticorrelated relationship between SST and CO₂F was reproduced.

Focusing on the CO₂F fluctuations associated with ENSO in the equatorial Pacific, Dong et al. (2016) analyzed the results of the CMIP5 ESMs. They showed that only a portion of CMIP5 ESMs (including MIROC-ESM) could reproduce the observed anticorrelated relationship between SST and CO₂F. Bellenger et al. (2014) evaluated the reproducibility of ENSO in the CMIP5 models. They reported that most CMIP5 climate models and ESMs underestimate the amplitude of the wind stress feedback by 20%–50%, and that only 20% of CMIP5 models have relative error within 25% of the observed value. There are many ESMs where the ENSO characteristics and/or the SST-CO₂F relationship are inconsistent with observations. Causes of this discrepancy should be addresses in future studies through, for example, multi-model analysis, and also process-based uncertainty estimation will be further required in initialized climate and carbon predictions as well as projections by ESMs.

Data availability

The model outputs of MIROC-ES2L (Hajima et al., 2019) are available through the Earth System Grid Federation (ESGF) (<https://doi.org/10.22033/ESGF/CMIP6.5602>). The model outputs of MIROC-ESM is also available at ESGF, <https://esgf-node.llnl.gov/projects/cmip5/>. The CMIP6 forcing data is version 6.2.1, and the CMIP5 forcing data is described at <https://pcmdi.llnl.gov/mips/cmip5/forcing.html>. The JRA55 reanalysis wind dataset is available at https://jra.kishou.go.jp/JRA-55/index_en.html. The COBE-SST2 dataset is available at <https://www.esrl.noaa.gov/psd/data/gridded/data.cobe2.html>. The postprocessing scripts used for this research and the data used in the figures can be obtained online (<https://osf.io/mpk52>).

Author contribution

MiW, HT, MaW, and MK contributed to the experiment design. MiW and HK embedded the ocean data assimilation system into the ESMs. MiW and TH performed the experimental simulations. MiW analyzed the model output and drafted the paper. All authors discussed the results, and commented on and edited the manuscript.

Competing interests

The authors declare that they have no conflict of interest.

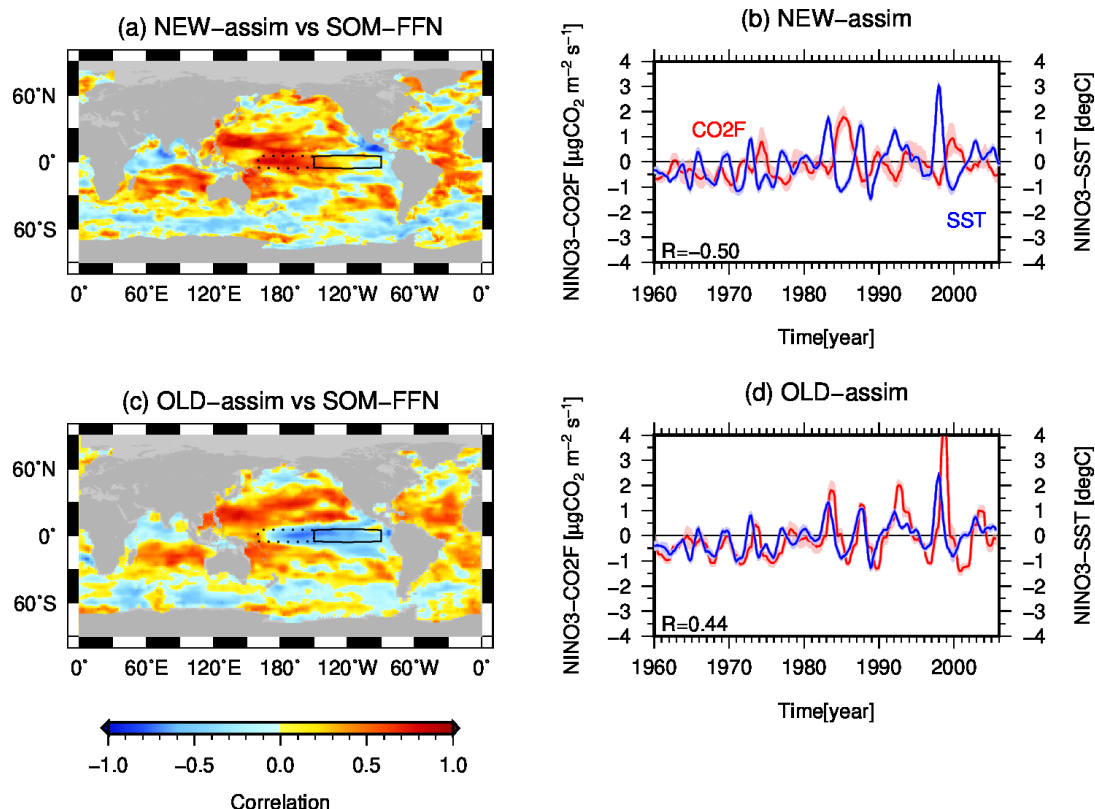

Figure 1. (a, c) Maps for correlation coefficient between monthly CO2F anomalies derived from SOM-FFN and that of (a) NEW-assim and (c) OLD-assim. The analysis period is from 1982 to 2005. The solid line boxes show Niño3 region (5°S – 5°N , 90° – 150°W) and the dotted line boxes show Niño4 region (5°S – 5°N , 160°E – 150°W). (b, d) Timeseries of the detrended NINO3-SST (blue line) and NINO3-CO2F (red line, positive upward) anomalies simulated with (b) NEW-assim and (d) OLD-assim. Values plotted are the one-year running mean, and shading in (b) and (d) shows the ensemble spread (1σ). R denotes the correlation coefficients between the detrended ensemble mean NINO3-SST and NINO3-CO2F anomalies, with one-year running mean filter applied.

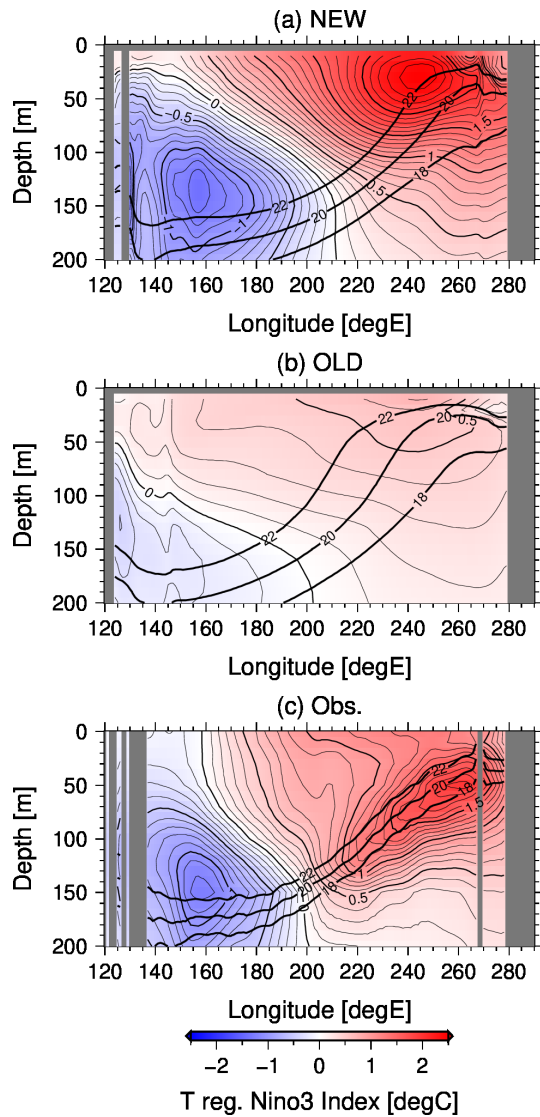

Figure 2. $\Delta p\text{CO}_2$ (dots) and its decomposition with changes in X (X=T, S, DIC, Alk), C(X), as well as Res. (Eq. (3)) evaluated in NEW-assim, NEW, OLD-assim, and OLD.

515 **Figure 3. Anomalies of equatorial ocean temperature regressed onto NINO3-SST anomalies for NEW (top), OLD (middle), and observations (bottom). Contour interval is 0.1 °C. Thick solid lines indicates the climatological-mean isotherms of the 18, 20, and 22 °C.**

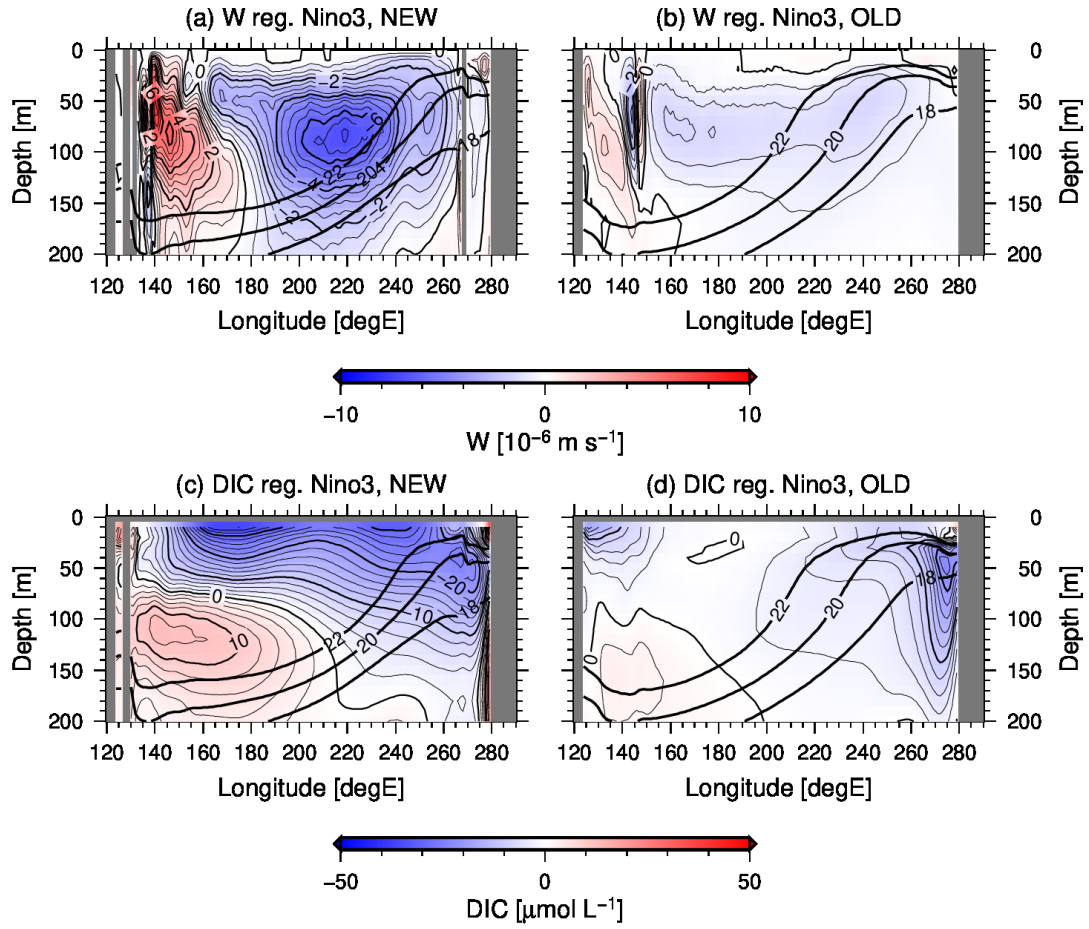

Figure 4. Anomalies of equatorial vertical velocity (upper panels) and DIC (lower panels) regressed onto NINO3-SST anomalies for NEW (left) and OLD (right). Contour intervals are $0.5 \times 10^{-6} \text{ m s}^{-1}$ in (a,b) and $2 \mu\text{mol L}^{-1}$ in (c,d), respectively. Thick solid lines indicates the climatological-mean isotherms of the 18, 20, and 22 °C.

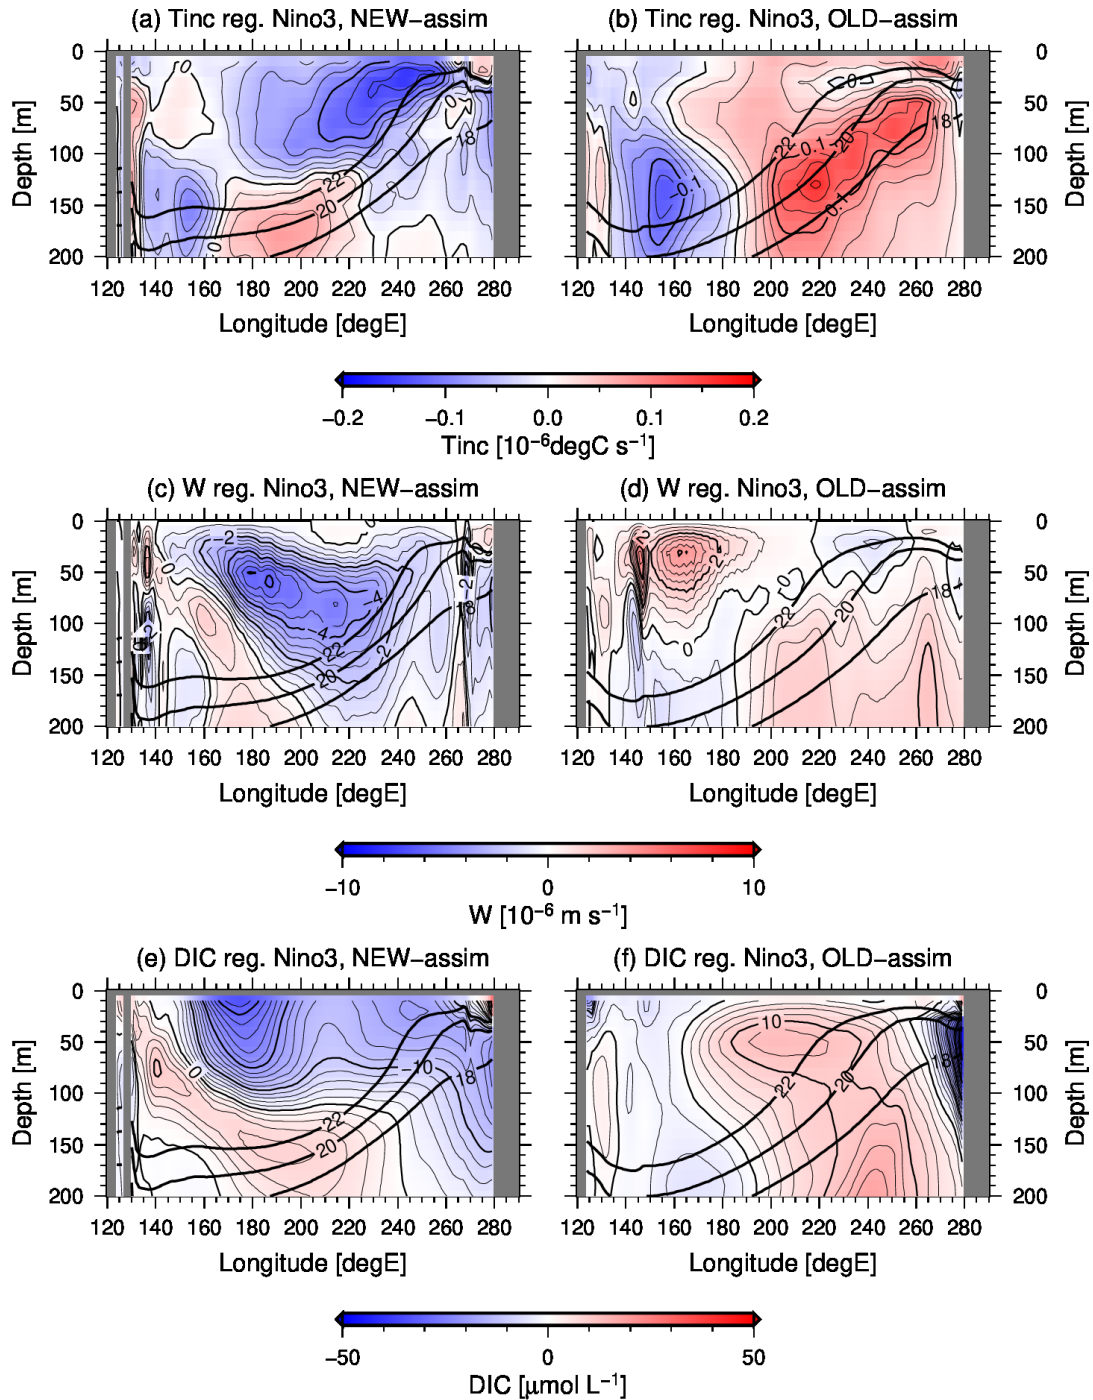

Figure 5. Equatorial temperature analysis increments (top panels), vertical velocity anomalies (middle panels) and DIC anomalies (bottom panels) regressed onto NINO3-SST anomalies for NEW-assim (left) and OLD-assim (right). Contour intervals are $0.02 \times 10^{-6} \text{ }^{\circ}\text{C s}^{-1}$ in (a,b), $0.5 \times 10^{-6} \text{ m s}^{-1}$ in (c,d) and $2 \mu\text{mol L}^{-1}$ in (e,f), respectively. Thick solid lines indicates the climatological-mean isotherms of the 18, 20, and 22 °C.

535 **Table 1. Correlation coefficients between detrended one-year running mean NINO3-SST and NINO3-CO2F anomalies in NEW-assim, NEW, OLD-assim, OLD, and observations. The correlations coefficients in NEW-assim, NEW, OLD-assim, and OLD are for the period from 1961 to 2005 (Figures 1 and S2), and that in observations are for the period from 1982 to 2005.**

	NEW-assim	NEW	OLD-assim	OLD	Observation
Corr. Coeff.	−0.50	−0.85	0.44	−0.67	−0.75

540 **Table 2. The intensity and period of ENSO in NEW, OLD, and observations calculated from the one-year running mean NINO3-SST anomalies for the period from 1961 to 2005.**

	NEW	OLD	Observation
Intensity of ENSO [°C]	1.17	0.43	0.80
Period of ENSO [yr]	5.0	4.5	3.5

545 **Table 3. The wind feedback computed as the monthly 10 m zonal wind anomalies in the Niño4 region which is regressed onto the monthly NINO3-SST anomalies and the vertical velocity feedback computed as the monthly vertical velocity anomalies at the depth of the 20 °C isotherm in the Niño3 region which is regressed onto the monthly NINO3-SST anomalies in NEW-assim, NEW, OLD, and OLD-assim. The wind feedback is also evaluated from the observation dataset.**

	NEW-assim	NEW	OLD-assim	OLD	Observation
Wind feedback [m s ^{−1} K ^{−1}]	0.92	0.92	0.48	0.46	1.02
Vertical velocity feedback [m s ^{−1} K ^{−1}]	−4.5×10 ^{−7}	−3.9×10 ^{−7}	4.1×10 ^{−7}	−4.9×10 ^{−7}	N/A
