Abstract: The wetland of Liao River Estuary (LRE) in northeast China is one of the best-preserved wetlands across the globe. However, it is extremely vulnerable to hydrological changes as well as other disturbances, particularly upstream river discharges and the reclamation from anthropogenic activities. In this study, a 3D hydrodynamic model was used to reproduce the flow patterns of the LRE and to explore the variation in salinity under different scenarios. Furthermore, the impact of river discharge and shoreline changes on the salinity distribution in the LRE were quantitatively analyzed and discussed through several simulation experiments. The model reasonably reconstructed the spatio-temporal variability and distribution of salinity in the Liao River Estuary and the wetlands across intertidal areas. Increases in runoff were demonstrated to significantly decrease the mean salinity values of the estuary, with changes in salinity negatively correlated to the longitudinal distance from the estuary mouth. Moreover, the shoreline change caused by the construction of Panjin Port was observed to have an obvious influence on the salinity distribution of the LRE, particularly in the lower reaches of the Pink Beach Wetland. Comparisons of the Liao River Estuary residual flow fields under different shorelines revealed that the establishment of the port resulted in the diffusion of the runoff from the Daliao River due to the obstruction of the port body, which

enhanced the tidal mixing effect and consequently weakened the dilution effect of fresh water entering the Pink Beach Wetland. Overall, the current study should be helpful for offering a greater understanding of *Suaeda heteroptera* vegetation degradation in the LRE, China, and also provides a new perspective in investigating the degradation mechanism in other estuarine wetlands.

Keywords: Numerical simulation, salinity distribution; coastline change, Liao River Estuary, coastal wetlands

1. Introduction

Estuaries are located at the interface area of rivers, land and the ocean, and are commonly described as enclosed or semi-enclosed bodies of water, where sea water is significantly diluted by the inflow of freshwater from upstream rivers. Accumulated freshwater can potentially regulate water and salinity at different temporal scales, and can offer the possibility to optimize suitable salinity conditions for animal and plant habitats within the estuarine zone. Estuaries are thus considered as highly productive ecosystems. As an essential component of estuaries, estuarine wetlands function as the bond connecting terrestrial and coastal water ecosystems, possessing features from both terrestrial and aquatic environments. Wetlands in estuaries are characterized by high biodiversity and hold the unique role of maintaining the ecological equilibrium (McClain et al., 2003). Estuarine wetlands can provide substantial ecological services, including flood control, sediment retention, the uptake of pollutants, carbon fixation and also act as habitats for fish, waterfowl and other biotic communities (Tsihrintzis et al., 1998; Weihoefer, 2011; Yang et al., 2018).

Estuaries form an environment with sinuous coastlines, where rivers, streams, or creek inlets meet the sea or ocean. The hydrological properties of estuaries create a complex physical environment due to the combined effects of upstream rivers and the adjacent ocean. Estuary circulations are primarily controlled by

1 freshwater discharge, the tidal range and tidal currents (Sassi & Hoitink, 2013; Veerapaga et al., 2019), and
2 are modified by winds, shorelines and topography (Alembregtse et al., 2016; Lai et al., 2018), which further
3 influence the processes of salinity transport and salt-wedge in estuary waters (Haralambidou et al., 2010;
4 Gong & Shen, 2011; Liu et al., 2019). Salinity changes in estuaries have been the focal point of much work
5 over the past few decades in order to understand saltwater intrusion mechanisms, with the majority of the
6 research based on on-site observations and numerical models. Early studies analyzed observation data to
7 investigate the salt intrusion phenomenon in estuaries, with further evaluations performed on estuary
8 mixing type, salt intrusion distance, salinity distribution and the current circulation (Pichard 1952, 1954;
9 Hansen & Rattray, 1965). This was followed by field surveys via instrumentation of Acoustic-Doppler-
10 Current-Profilers (ADCP) and Conductivity-Temperature-Depth (CTD), whereby researchers investigated
11 the salinity distribution characteristics and the salt transport mechanisms in the Hudson River estuary
12 (Bowen & Geyer, 2003; Lerczak & Geyer, 2006). Studies suggested that the salt intrusion in an estuary is
13 maintained by two opposite longitudinal transport processes: i) An advection resulting from fresh water
14 outflow, which tends to drive salt out of the estuary; and ii) a down gradient advection, which drives salt
15 landward (Lerczak & Geyer, 2006). The salinity patterns in estuaries were also demonstrated to be the
16 result of additional factors, such as the longitudinal advection and vertical mixing (MacCready, 2010;
17 Scully & Geyer, 2012).

18 The development and application of numerical models have been a key component of research on the
19 salt transport and saltwater intrusion in estuarine waters at high spatial and temporal resolutions. For
20 example, Zhao et al. (2010) simulated wetland-estuarine-shelf interaction processes at the Plum Island
21 Sound and Merrimack River system in the Massachusetts coast using the three-dimensional (3D)
22 unstructured-grid, finite volume coastal ocean model (FVCOM), where the water exchange was observed

to vary with the magnitude of freshwater discharge and wind conditions. Gong (2011, 2018) employed the Environmental Fluid Dynamics Code (EFDC) and the Coupled-Ocean-Atmosphere-Wave-Sediment Transport (COAWST) to investigate the effects of local and remote winds and wind waves on salt intrusion in the Modaomen and Pearl River estuaries, respectively, with conclusions having an applicability to other partially mixed estuaries under the threat of salt intrusion. Popescu et al. (2015) presented a 3D hydrodynamic model to understand the hydrodynamics of the Danube Delta wetlands, demonstrating the strong impact of the Danube River variable discharges on the habitats and the overall ecological status of the delta. Andrews et al (2017) applied the 3D hydrodynamic model to examine the impacts of anthropogenic changes (land use changes, levee construction, channel modifications etc.) on the physical characteristics and salt intrusion processes at the San Francisco Estuary. Wang et al (2019) combined the FVCOM model with long-term field survey data to investigate the seasonal variability of currents and salinity in the Indus River Estuary. Results revealed that the salinity intrusion distance was principally controlled by river discharge in the estuary, while the seawater intrusion was significantly impacted by tidal forcing in the absence of river runoff. Tian (2019) combined field data collected in the Chester River Estuary with FVCOM to identify the driving factors and their relative importance in controlling the saltwater intrusion variability across time. Results demonstrated that river discharge was the primary factor controlling saltwater intrusion changes over inter-annual time scales, while sea surface levels dominated the seasonal variations (Tian, 2019). Estuarine salinity has a significant effect on the growth of coastal wetland plants and plays an important role in maintaining the ecological health of estuarine wetlands (Song et al. 2009). Despite this, studies on the spatial and temporal distribution of salinity in estuarine wetlands are limited, with most work generally focusing on salinity transport and saltwater intrusion mechanisms along the estuaries (Ralston et al., 2008; Haralambidou et al., 2010; Veerapaga et al, 2019; Wang et al., 2019).

The Liao River in northeastern China is one of the seven largest rivers in the country and ends at the LRE located at the top of Liaodong Bay (Fig. 1a). Due to the recent rapid urban sprawl and growth in population, water consumption has increased dramatically in the Liao River basin. In addition, the upstream closure projects have directly led to a sharp decrease of the downstream runoff of Liao River into the Liaodong Bay, which may further affect the exchange and mixing of salt water and fresh water in the estuary (Ralston et al, 2008; Gong et al, 2011). Panjin Port is located on the southeast of the LRE, adjacent to the Daliao River (Fig. 1b). The port was founded in 1995, completed in 1999, and following more than 10 years of continuous expansion, the existing land area has reached 230,000 m². The construction of Panjin Port is of great importance for the development of the local economy, yet its construction has also been problematic. The large area of marine reclamation has resulted in drastic changes in the southeast coast of the LRE since 1995 (Fig. 1b and c). Large areas of marine reclamation can alter both the local topography and the original coastline (Jia et al., 2018). Changes in the shoreline will have an impact on the characteristics of the original flow field, which can consequently affect the transport processes of ocean materials, including sediment transport, pollutant diffusion and salinity distribution (Alebrektse et al., 2016).

Suaeda heteroptera is one of the most common pioneer salt-tolerant plants in the LRE. Large area of *Suaeda heteroptera* community grows in intertidal zone along the east coastline of the LRE, forming a unique natural landscape which is known as the Pink Beach Wetland. According to satellite images and on-site observations, the wetlands in the LRE have experienced severe degradation over the past decade, particularly in the Pink Beach Wetland (PBW) close to the northwest of Panjin Port (Wang et al., 2020). Much effort has been made to investigate the growth mechanisms and influencing factors of vegetation *Suaeda heteroptera* in salt marshes (Song et al., 2009; Wang et al., 2010; Sun et al., 2016). Experiments

implemented by Li et al (2018) have revealed that high salinity can significantly restrain the growth of salt mash vegetations (*Suaeda heteroptera* and *Phragmites australis*). However, the impacts of runoff decrease and shoreline changes on the temporal and spatial distributions of salinity, and the relationship between wetland degradation and anthropogenic activities in the LRE, are not yet fully understood.

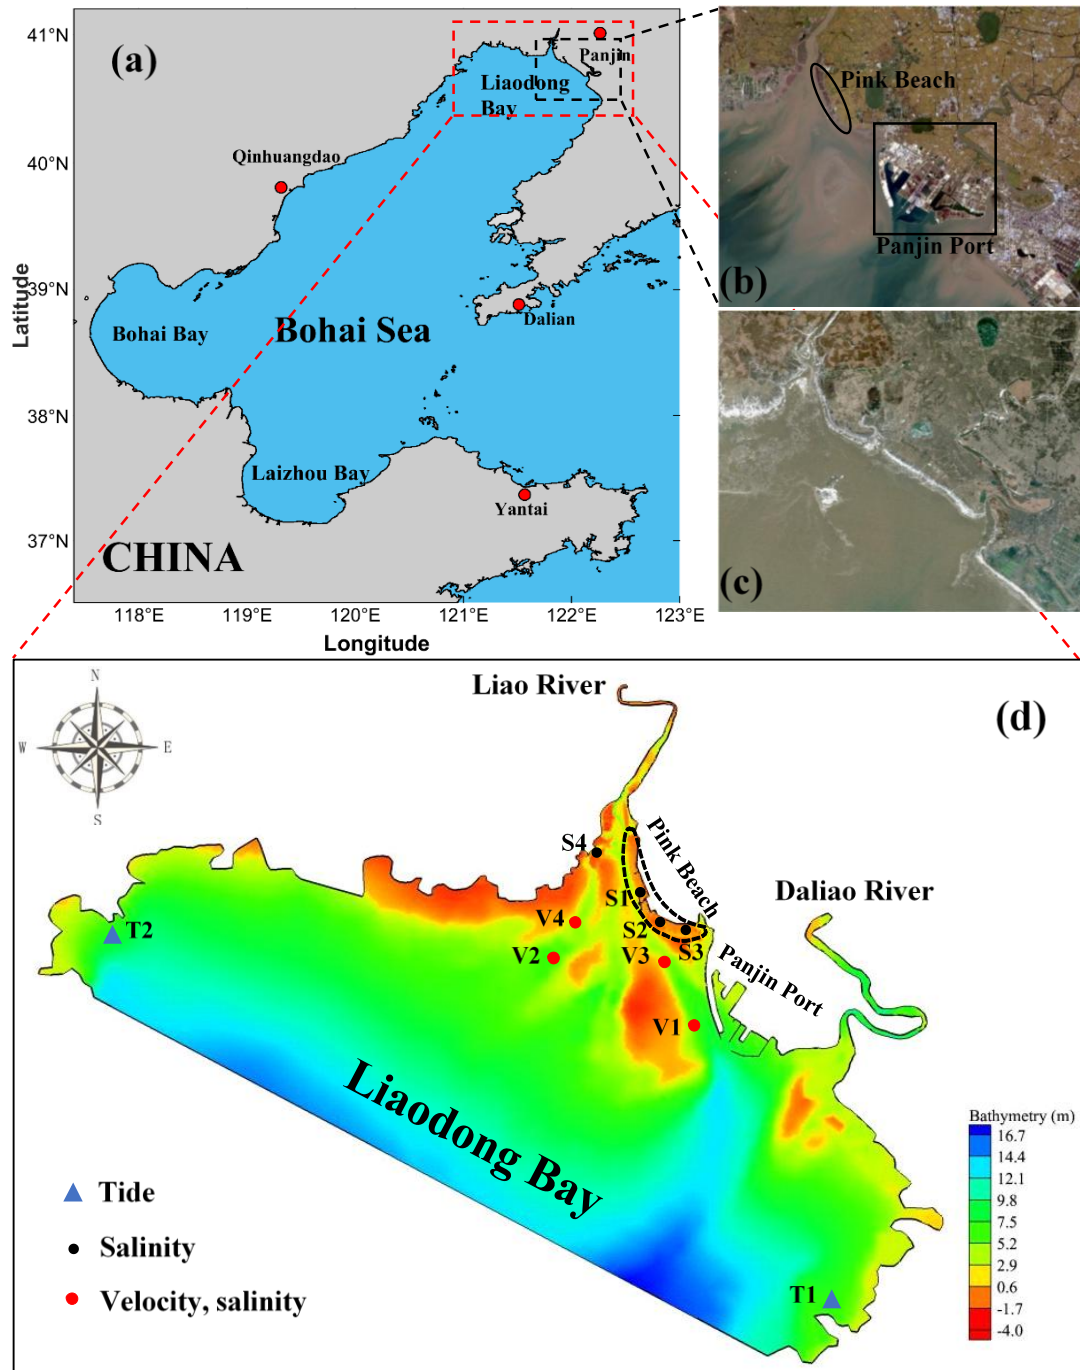

Figure 1. Sketch maps of the study domain. (a) The geographical position of the LRE. (b) The

Landsat image of intermediate and eastern area of the LRE in 2019 (from Geospatial Data Cloud <http://www.gscloud.cn/sources/>). The black elliptical shape represents the PBW region, and the black rectangular denotes the Panjin Port area. (c) The Landsat image of eastern LRE in 1995. (d) The bathymetry of the LRE waters (positive values represent water depth and negative values indicate land elevation), the observation stations and analysis gauges. The blue triangles denote the tidal stations, the red circles are the tidal flow and salinity observation stations, while the black circles represent the analysis gauges used for salinity comparison.

In this study, the FVCOM model was combined with field observations to investigate the effect of anthropogenic shoreline changes on the salinity distribution in the LRE. The principle aims of this study are to: (1) evaluate and quantify the effect of shoreline changes resulting from the port construction on estuary circulations and salinity distributions in the LRE; (2) explore the potential influence of these variations on growth of *Suaeda heteroptera* in tidal wetlands in the LRE; and (3) provide a reference for wetland conservation and water resource utilization in the LRE. The rest of the paper is organized as follows. A brief introduction of the study area is described in Section 2. Section 3 provides a description of the FVCOM model and demonstrates the implementation of the modeling system and model validation, including tidal level, flow and salinity. The effects of shoreline change resulting from port construction on residual flow and the spatial-temporal distribution of salinity in the LRE are analyzed and discussed in detail in Section 4. Finally, the general conclusion of the manuscript is detailed in Section 5.

2. Study area

The LRE, situated in the northwest of Liaoning Province, China, is a funnel-shaped shallow estuary that exhibits a decrease in width from 20 km at the mouth to 1 km at the upstream reach. It is a momentous ecological economic zone in the north of the Liaodong Bay, playing an important role in the comprehensive

development of the marine industry and fishing economy in northeastern China. The bathymetry of the LRE is complicated, with the formation of many shallow shoals due to sediment deposition. The water depth ranges from < 3 m in the shoals to < 7 m in the main channels. The tidal feature in Liaodong Bay fundamentally belongs to semidiurnal tide. In addition, except the region along the coast of Liaoning Province in which semidiurnal tide predominates, most marine domains are under the control of diurnal tide (Liu et al., 2005). The upstream river network of the LRE is relatively simple, mainly dominated by the Liao River and is also affected by the river discharge from the Daliao River. The multi-year average river discharge of the Liao River ranges from $101 \text{ m}^3/\text{s}$ in the dry season to $285 \text{ m}^3/\text{s}$ in wet season (Qiao et al., 2018), barely reaching $450 \text{ m}^3/\text{s}$ under extreme precipitation conditions.

3. Methods

3.1 Model description

The FVCOM was adopted to simulate tidal flow and salinity in the LRE. It is a three-dimensional ocean model which was originally developed by (Chen et al. 2003, <http://fvcom.smast.umassd.edu/fvcom>) based on primitive equations and improved by researchers at the University of Massachusetts-Dartmouth (UMASSD) and Woods Hole Oceanographic Institution (WHOI) (Chen et al., 2006a). Previous applications include research on large lakes, coastal estuarine regions, and regional ocean areas (Gronewold et al., 2019; Lin & Fissel, 2014; Lai et al., 2018). The modelling system uses the finite volume method with the capability to deal with horizontal unstructured triangular cells, which is well fitted to irregular coastline and small scale simulations (such as estuarine wetlands) with high resolution. The application of terrain-following coordinates results in an improved capacity to solve complex bathymetric conditions (Chen et al., 2006b). In addition, the ocean circulation model employs the modified level 2.5 Mellor and Yamada and Smagorinsky turbulent closure schemes for vertical and horizontal mixing.

3.2 Model configuration

The model domain covers the whole sea region located at the top of the Liaodong Bay, including the Liao River and the Daliao River, extending from the 40.303° to 40.710° northern latitudes and the 121.029° to 122.031° eastern longitudes. In order to visually reflect the shoreline changes resulting from the construction of Panjin port, two coastlines of the port area were manually extracted from Landsat image collected in 1995 and 2019 (from Geospatial Data Cloud, <http://www.gscloud.cn>) using ArcGIS software. The remaining coastline of the LRE was manually extracted from Google Earth software (with higher spatial resolution). As shoreline changes in other area of the LRE were relatively less significant over the time span, two port coastlines were then respectively reconnected with the same remaining coastline in the finite-element Surface-water Modeling System by Acquaveo (Chen et al., 2006), which was applied to generate an unstructured triangular mesh for the LRE domain. The bathymetry of the computation domain was derived from the Navigation Guarantee Department of the Chinese Navy Headquarters (China Navigation Publications Press) and the topographic survey data in the upstream of the LRE that we measured. The total number of grid nodes and elements were 9501 and 17938 for grid 1995 (Fig. 2b), and 13699 and 25928 for grid 2019, respectively (Fig. 2c). The largest lateral and longitudinal lengths of the model domain were 113 km and 67 km, respectively, while the spatial resolution of the model grids varied from 2500 m at the external open boundary to 60 m at the intertidal area of the wetland domain.

The three-dimensional baroclinic mode with 11 vertical sigma levels was adopted for the modelling system, with the external and internal mode time steps set to 2 s and 10 s, respectively. The model was only driven by surface elevation, salinity and temperature at the open boundary. The open boundary condition for surface elevation and vertically-averaged velocity was original FVCOM setup (ASL) and that for the perturbation of salinity and temperature was Blumberg and Kantha (BKI) condition (Blumberg and Kantha,

1985). The tidal water level at each open boundary node was derived from the Global Tide Model available within the MIKE 21 Toolbox (DHI, 2017). The velocity in the open cell is computed using the linear or nonlinear momentum equations. The open boundary condition for salinity was set to 32 PSU at the sea surface and interpolated between 32 and 34 PSU along the sigma layers, and that for temperature was specified as constant 15 °C from the surface to the bottom. The startup u and v values were specified as zero. The initial conditions for salinity and temperature were based on the quasi-steady result derived by running the model for approximately four months. Sea surface heat fluxes and wind forcings were omitted for simplicity. Furthermore, four case studies were set up based on two computational grids and two different river discharge conditions, as illustrated in Table 1. Following this, the river discharges of the Liao River and Daliao River were set to 25 m³/s and 48m³/s (285 m³/s and 266 m³/s), indicating a sharply decreased mean runoff (normal mean runoff) circumstance, respectively (Qiao et al, 2018).

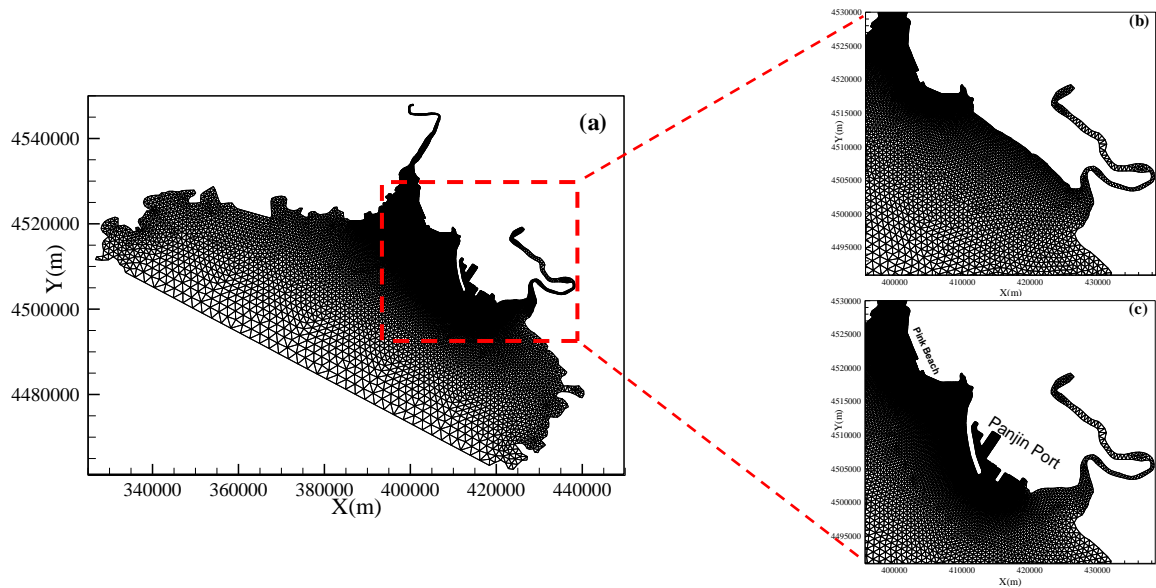

Figure 2. Mesh sketch of the LRE (a) and detailed meshes for the Panjin Port region in 1995 (b) and 2019 (c).

Table 1. Model case study settings.

Case Study	Grid	River Discharge (m ³ /s)	
		Liao River	Daliao River
Case1	2019	25	48
Case2	2019	285	266

Case3	1995	25	48
Case4	1995	285	266

3.3 Model validation

To validate the model's performance in the simulation of the tidal dynamics and salt transport in LRE, the simulated results were compared with the available measured data. Thereinto, two tide level stations (T1 and T2), four tidal flow observation stations (V1, V2, V3 and V4), two salinity measuring gauges (V1 and V2) and four wetland salinity analysis sites (S1, S2, S3 and S4) were selected to evaluate and analyze the model performance in the study domain. Table. 2 gives the specific coordinate information about the eight stations. The model simulations cover the period from 20 April to 10 September 2018. The tide level was verified from 0:00 on 1st May to 23:00 on 31 May 2018. The periods of tidal flow validation were divided into neap tide and spring tide, of which the neap tide period was from 11:00 on 8 June to 10:00 on 9 June, 2018, and the spring tide period from 6:00 on 15 June to 5:00 on 16 June, 2018. The salinity data was measured at V1 and V2, with a validation period from 5:00 on 10 September to 4:00 on 11 September 2018 for V1, and from 6:00 on 10 September to 5:00 on 11 September 2018 for V2.

The comparison between modelled and observed data was quantified using the root mean square error (RMSE) and the predictive skill score (Skill). The magnitude of the RMSE indicates the average deviation between the simulated results and the observed data, while the predictive skill score represents the degree to which the simulated value fits the measured value (1 = perfect fit, 0 = complete difference). The RMSE and Skill are defined as follows:

$$RMSE = \sqrt{\frac{\sum_{i=1}^n (M_i - O_i)^2}{n}} \quad (1)$$

$$Skill = 1 - \frac{\sum_{i=1}^n (M_i - O_i)^2}{\sum_{i=1}^n (|M_i - \bar{O}| + |O_i - \bar{O}|)^2} \quad (2)$$

where M_i and O_i represent the modeled results and observed values, respectively, \bar{O} indicates the mean of the observed values, and n is the number of observed data points.

Table 2. Coordinate information of gauging stations

Stations	Longitude (°E)	Latitude (°N)
T1	122.150	40.364
T2	121.065	40.790
V1	121.913	40.739
V2	121.744	40.790
V3	121.849	40.796
V4	121.776	40.836
S1	121.839	40.840
S2	121.892	40.804
S3	121.924	40.805
S4	121.767	40.886

Figure 3 presents the tide level comparison results. The simulated water levels at T1 and T2 are observed to agree well with the measured data. In general, the amplitudes of the modeled results are consistent with the observations, with a maximum phase difference of less than 30 minutes. The harmonic analysis was also performed in this study, the model results are in good agreement with the observations for the main component M2 in the two stations. The deviations between the model and field data are smaller than 9 percent for the amplitude and 10 degrees for the phase. Despite this, several significant errors are observed between the simulated high and low tide levels and the observed values. This may be attributed to the inaccurate open boundary water level conditions. The comparisons of the simulated and measured flow speeds and directions during neap and spring tides are presented in Figure 4 and Figure 5, respectively. In general, the modeled tidal flow exhibits a better match with the observation data in neap tide compared to spring tide. The poorer spring tide fitting results may be a result of the following: (1) The open boundary conditions adopted in the model may be inaccurate for certain periods; (2) the bathymetry used in the model may differ to that of the study area due to recent sediment deposition; and (3) the model employed a uniform bed roughness coefficient across the whole area. Figure 6 displays the comparisons of simulated and observed salinity at V1 and V2. The simulated salinity is in good agreement with the measured data, with broadly consistent trends in variation between datasets. Table 3 gives the results from the error

quantification analysis of the simulated tide level (ζ), tidal flow (\bar{U}) and salinity (\bar{S}). The Skill scores for the T1 and T2 tide levels are both greater than 0.95, while flow velocities exceed 0.80. The results indicate that the model established in this paper can accurately reproduce the hydrodynamic processes in the LRE. The determined Skill values for salinity indicate that the model effectively reproduces the salinity variations at V1, yet slightly under-estimates the salinity at V2. The high simulation accuracies of the water level, currents and salinity determined by the proposed model in the study area demonstrates that the model is suitable for further studies on the salinity distribution in the LRE.

4 Results and discussion

4.1 Effect of river discharge on salinity distribution in the LRE

To explore the effect of river discharge on salinity transport in the LRE, two experimental cases were established (Case 1 and Case 2). An average value of 50-h was chosen to reflect the irregular semi-diurnal tidal characteristics of the LRE. The salinity distribution characteristics at the surface and bottom layers are generally consistent due to the shallow water depth in the LRE, salinity difference along the vertical was inapparent, thus the vertical averaged salinity value was selected for analysis. The 50-h averaged salinity distributions of the LRE during spring and neap tides under different runoff conditions are shown in Fig. 7 and Fig. 8. For Case 1, the salinity values in the middle of the estuary during neap and spring tides are maintained between 16-28 PSU and show a low longitudinal gradient from downstream to upstream. In Case 2, the salinity values of the middle LRE decrease significantly and vary between 4-20 PSU, the longitudinal salinity gradient becomes higher compared with Case 1. As the tidal current movement strengthens during the spring tide period, the saltwater intrusion distance in the estuary consequently increases compared to that during the neap tide period.

To quantify the effect of river discharge on the salinity of LRE, the 30-day averaged salinities of eight stations at the surface and bottom layers for Case 1 and Case 2 were compared in Fig. 9. The salinity of the LRE is observed to decrease dramatically as the river discharge increases to mean level. As shown in Fig. 9(b), the averaged salinities of the eight sites in Case 2 decreased by 84.9%, 28.8%, 14.6%, 68.1%, 16.5%, 40.0%, 46.5% and 46.1%, respectively, compared with those in Case 1. As a result, the salinity of the LRE varies with runoff condition and tidal strengthening. Variation in river discharge exerts a significant effect on the longitudinal distribution of salinity in the estuary. Due to river closure projects in the upper reaches of the Liao River and increasing water consumption by population, the mean river discharge from the Liao

River into the Liaodong Bay has decreased sharply, which directly weakening the river flow's resistance to the tides and further strengthen the salt intrusion in the estuary. In addition, decrease in runoff will alter the tide duration in estuary. For vegetation in salt marshes, the prolonged retention time of salt water will further increase duration of salt stress which may result in negative effects on vegetation growth. Thus, as river discharge in the head of LRE sharply dropped over the past decade, it is reasonable to speculate that the corresponding salinity increase and prolonged salt water retention will have restrained effects on growth of *Suaeda heteroptera* in the estuarine wetlands, which could potentially lead to the degradation of salt marshes and long-term instability of estuary ecosystem in the LRE.

Figure 9. Panel (a) comparison of 30-day averaged salinity at the eight stations for Case 1 and Case 2; Panel (b) the decrease percentage of salinity values in Panel (a).

4.2 Effect of shoreline change on salinity in the LRE

The majority of salt marsh plants in the LRE grow on the tidal flats along the coast, and are thus submerged by sea water at high tide and are exposed at low tide. This unique growth environment complicates the research on the degradation mechanisms facing such vegetation. Consequently, we applied numerical

simulations to overcome this obstacle, focusing on the influence of shoreline change caused by anthropogenic activity on the salinity distribution of LRE. In addition, we further discussed the potential relationship between shore change and tidal wetland degradation in the LRE. To investigate the influence of shoreline change caused by the port construction on the salinity distribution in the LRE, the computational grids generated by two shorelines in 1995 (pre-port construction) and 2019 (post-port construction) were adopted for salinity simulations in the LRE. The simulated results of the two grids were then compared and analyzed. Figures 10 and 11 show the average salinity distribution calculated by grid 1995 during a spring tide and a neap tide under different runoff conditions, respectively. In general, the salinity of the LRE in 1995 exhibits a significant decrease under high river discharge, with the longitudinal salinity gradient becoming more pronounced. It can be seen from Fig. 8 (9) and Fig. 10 (11) that salinity distribution during spring tide (neap tide) in 1995 evidently differs from that in 2019, especially at the east LRE where the Panjin Port built. For a more intuitive comparison, the isohalines of the LRE under low and normal mean runoff conditions were plotted using the results from the two grids, as shown in Fig. 12. The green isohalines (grid 2019) are located upper the red isohalines (grid 1995) in the estuary waters during both runoff conditions, particularly in the eastern region of downstream PBW, adjacent to the Panjin Port.

To quantify the influence of shoreline changes on the salinity of the LRE, we compared the 30-day averaged salinities determined via the two grids at the eight monitoring sites as shown in Fig. 13. For Case1 and Case3 (low mean runoff condition), following the construction of the Panjin Port, the averaged salinities of the eight stations (S1, S2, S3, S4, V1, V2, V3 and V4) increased by 4.4%, 6.2%, 7.9%, 0.7%, 4.5%, 2.6%, 5.1%, 2.6%, 5.1% and 2.3%, respectively, and that for Case 2 and Case 4 (normal mean runoff condition) increased by -0.6%, 14.5%, 20.9%, -1.3%, 6.9%, 2.2%, 11.0% and 1.4%, respectively. These results indicate that the shoreline change caused by the extensive sea reclamation for the construction of

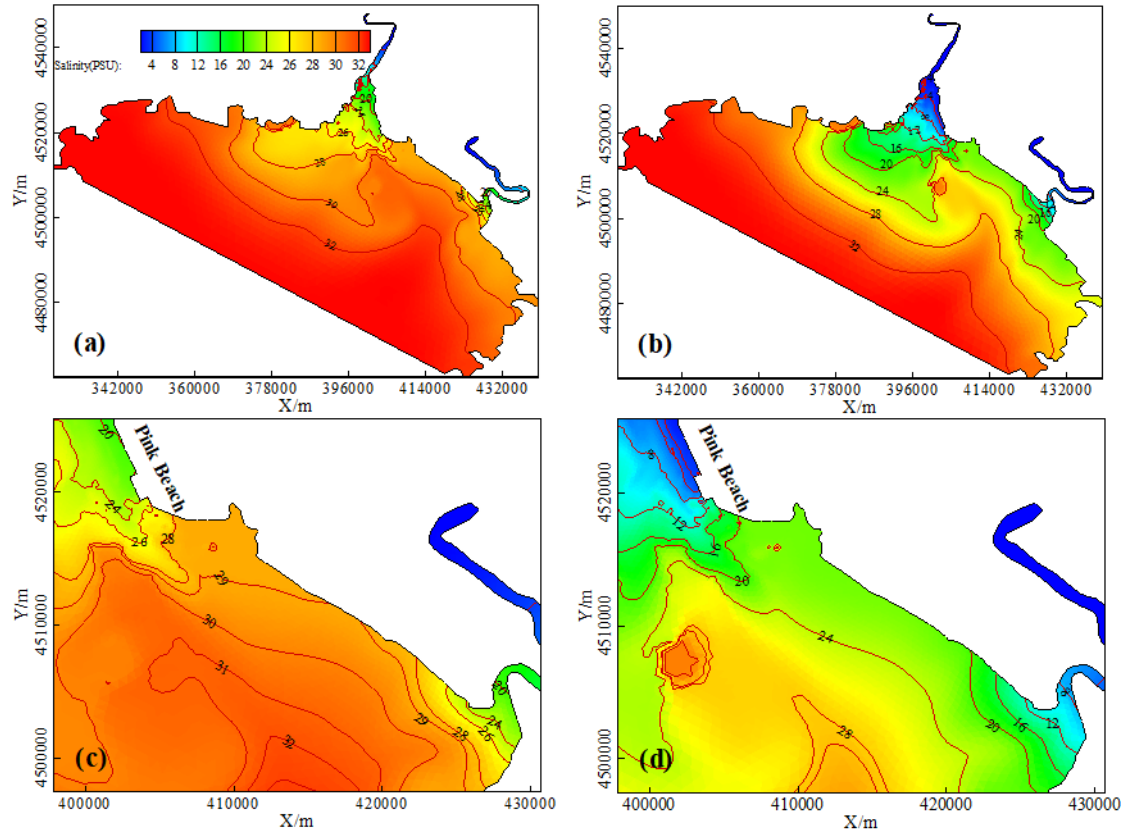

Figure 10. Simulated distribution of 50-h averaged salinity in the LRE during a spring tide. Panel (a) and panel (c) for Case3; panel (b) and panel (d) for Case4.

Figure 11. Simulated distribution of 50-h averaged salinity in the LRE during a neap tide. Panel (a) and panel (c) for Case3; panel (b) and panel (d) for Case4.

Figure 12. Comparison of 50-h averaged isohalines simulated using grid 1919 (green solid line) and grid 1995 (red solid line) in low runoff condition (left panel, Case 1 and Case 3) and normal mean runoff condition (right panel, Case 2 and Case 4).

Panjin Port has considerable effect on the salinity distribution in the LRE, particularly in the downstream PBW (S2, S3) on northwest Panjin Port. This increase is observed to be greater under normal mean runoff condition compared to low mean runoff condition, with a maximum increase in salinity over 4 PSU.

Figure 13. 30-day averaged salinities of the eight stations derived from the grid 1995 and grid 2019 in (a) low mean runoff condition; (b) normal mean runoff condition.

4.3 Effect of shoreline change on residual flow in the LRE

To illustrate the potential factor leading to the salinity increase in south-east PBW, we analyzed the residual flow patterns of the LRE with and without the Panjin Port. Comparison of the residual flow fields of the LRE under the two shoreline conditions as shown in Fig. 14 demonstrated that a residual flow induced by the runoff from the Daliao River traveled parallelly to the coastline to the downstream of the PBW before port was built. Following the port establishment, under the obstruction of groyne and port, the residual current near the port exhibited significant variation in both magnitude and direction. Prior to the port construction, the runoff-induced residual flow from the Daliao River travelled along the shoreline to the lower reaches of the Pink Beach Wetland, the continuous supply of fresh water can dilute the sea water and decrease the salinity, also the nutrients transported by residual flow can be benefit for vegetation growth. The port facilitated the bifurcation of the flow and generated several gyres, which results in a decrease in water mass and slows down the flow to the downstream of PBW. It is reasonable to assume that the obstruction of the port body enhanced tidal mixing effect resulting in the diffusion of the Daliao River runoff, weakening the fresh water dilution effect on the seawater, which is responsible for the higher salinity in the PBW following the shoreline changes in 2019.

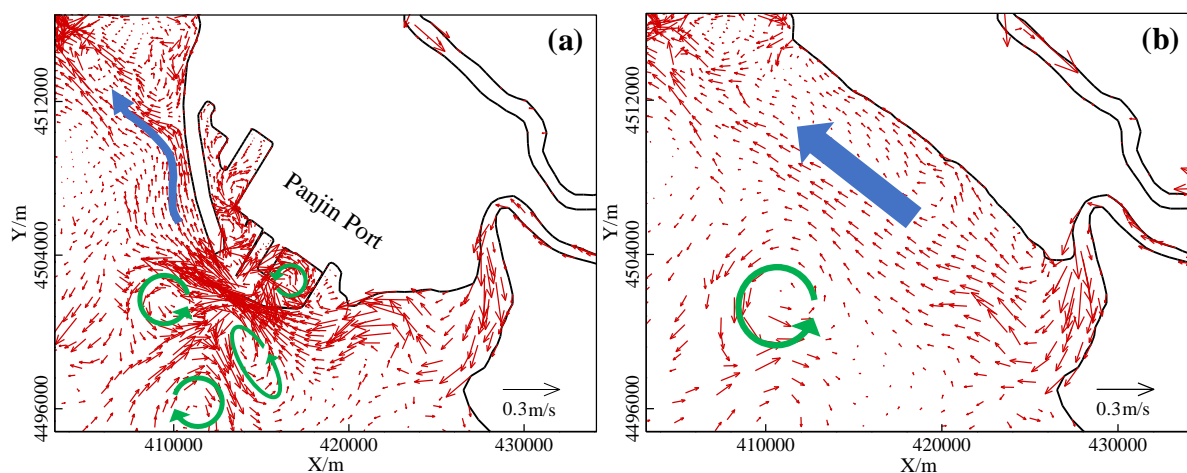

Figure 14. Depth-averaged residual flow calculated by grid 2019 (a) and grid 1995 (b). Blue filling arrows indicate residual currents induced by runoff from Daliao River to the downstream of PBW. Green annular

arrows represent residual gyres.

5 Conclusions

In this paper, a three-dimensional numerical model was applied to investigate the influences of river discharge and shoreline changes on the salinity distribution in the LRE. Two runoff conditions were set to represent different water seasons in the estuary. Data derived from Landsat satellite imagery and adapted using Google Earth software was employed to extract the LRE shorelines in 1995 and 2019. These were then used to generate the computational grids for tidal current and salinity distribution simulations of the LRE before and after the construction of Panjin Port. Simulation results indicate that both the decrease in river discharge and port construction induced shoreline change have noticeable effects on the longitudinal distribution of salinity in the LRE. Runoff decrease can significantly strengthen salt intrusion in estuary waters, resulting in salinity increase in wetland waters, which is unfavourable for vegetation growth. Furthermore, the changes in shoreline triggered by the construction of Panjin Port has noticeable effect on the salinity transport in the LRE, with the Pink Beach Wetland in northwest Panjin Port observed to be the most effected. There is a rise in the water salinity amongst the wetlands located within the lower reaches of the Pink Beach Wetland following the construction of the port, with a maximum increase in salinity over 4 PSU. The obstruction effect of port strengthens the tidal current mixing and decreases the residual flow to the downstream of PBW, which further reduces fresh water supply to the wetland, leading to a rise in water salinity.

The ecological degradation of wetlands in the LRE has become more and more severe in the past decade, especially in the PBW. This is attributed to long-term disturbances resulting from anthropogenic activity, including river closure projects, agriculture irrigation, and coastal constructions. Despite this, key physical processes in the LRE have yet to be systematically investigated and understood in terms of river discharge,

wind, wave and complex terrain conditions. The influences of wind stress, estuary topography variations and water resource utilization in upper rivers on the spatial-temporal distribution of salinity in the LRE will be the focus of future work.

Author contributions.

All authors contributed to the design and development of the work. The experiments were originally carried out by MZ and TX. HJ carried out the data analysis. MZ and TX built the model and wrote the paper.

Competing interests.

The authors declare that they have no conflict of interest.
