35

36 **Abstract.** Over the past decade, our understanding of the Indian Ocean has advanced through concerted efforts toward  
37 measuring the ocean circulation and its water properties, detecting changes in water masses, and linking physical processes  
38 to ecologically important variables. New circulation pathways and mechanisms have been discovered, which control  
39 atmospheric and oceanic mean state and variability. This review brings together new understanding of the ocean-atmosphere  
40 system in the Indian Ocean since the last comprehensive review, describing the Indian Ocean circulation patterns, air-sea  
41 interactions and climate variability. The second International Indian Ocean Expedition (IIOE-2) and related efforts have  
42 motivated the application of new technologies to deliver higher-resolution observations and models of Indian Ocean  
43 processes. As a result we are discovering the importance of small scale processes in setting the large-scale gradients and  
44 circulation, interactions between physical and biogeochemical processes, interactions between boundary currents and the  
45 interior, and between the surface and the deep ocean. In the last decade we have seen rapid warming of the Indian Ocean  
46 overlaid with extremes in the form of marine heatwaves. These events have motivated studies that have delivered new  
47 insight into the variability in ocean heat content and exchanges in the Indian Ocean, and climate variability on interannual  
48 to decadal timescales. This synthesis paper reviews the advances in these areas in the last decade.

## 49 **1. Introduction**

50 The physical processes taking place in the Indian Ocean and overlying atmosphere underpin the variability evident in  
51 monsoons, extreme events, marine biogeochemical cycles, ecosystems, and ultimately human experience. The Indian Ocean  
52 rim countries, accounting for one third of the Earth's human population, depend on this ocean for food and resources, and  
53 are dramatically impacted by its variability (Hermes et al., 2019). Increasing our understanding of interactions between  
54 geologic, oceanic and atmospheric processes that control the complex physical dynamics of the Indian Ocean region is a  
55 priority for the second International Indian Ocean Expedition (IIOE-2). The questions about the Indian Ocean circulation,  
56 climate variability and change that IIOE-2 seeks to address are: 1) how have the atmospheric and oceanic circulation of the  
57 Indian Ocean changed in the past and how will they change in the future; 2) how do these changes relate to topography and  
58 connectivity with the Pacific, Atlantic and Southern oceans; and 3) what impact does the circulation, variability, and change  
59 have on biological productivity and fisheries.

60 This focus on the Indian Ocean has motivated new international efforts in field campaigns and modelling studies, and  
61 leveraged advances in global observations that contribute to the Indian Ocean Observing System (IndOOS; Beal et al.,

62 2020). The Argo profiling float array (Roemmich et al., 2012) reached full coverage in the Indian Ocean in 2006, the RAMA  
63 moored buoy array (McPhaden et al., 2009) has now delivered multi-year time series of tropical oceanic and atmospheric  
64 variability, with some sites dating back to 2000. Satellite observing continues to provide observations vital to interpreting  
65 spatial and temporal variability in the *in situ* observations, and new technology is now enabling high resolution observations  
66 of boundary current variability and small scale processes. Thus, since the reviews of Schott and McCreary (2001) and  
67 Schott et al. (2009), the spatial coverage of observations and length of time series have increased substantially such that the  
68 signals of many previously unresolved processes are now able to be observed.

69  
70 These new higher-resolution observations and companion improvements in model simulations have highlighted the  
71 importance of small scale processes in setting the large-scale gradients and circulation, interactions between physical and  
72 biogeochemical processes, interactions between boundary currents and the interior, and between the surface and the deep  
73 ocean. Overlaid on these interior Indian Ocean processes, ocean warming due to increasing greenhouse gas concentrations  
74 has been shown to be pervasive and relentless (Wijffels et al., 2016), and extending to abyssal depths (Johnson et al., 2008a;  
75 Desbruyeres et al., 2017). The Indian Ocean plays a key role in the global climate system, enabling upwelling of the  
76 Meridional Overturning Circulation lower cell through strong diffusive mixing (Lumpkin and Speer, 2007; MacDonald et  
77 al., 2009; Talley, 2013) and exporting the largest poleward heat flux of all Southern Hemisphere basins (Roxy et al., 2014).  
78 In recent decades, the upper 700 m of the entire Indian Ocean has warmed rapidly (Desbruyères et al, 2017) . In the southern  
79 Indian Ocean, the warming was directly linked primarily to heat advection from a strengthened ITF and, secondarily, to a  
80 decrease in mean air-sea flux cooling (Li et al., 2017b; Zhang et al., 2018a). This coupling shifted the balance of global  
81 warming between the ocean and atmosphere, accelerating ocean warming and causing a hiatus in the warming of Earth's  
82 surface atmosphere (Section 6). Marine heatwaves have emerged as an increasing threat to marine ecosystems as ocean  
83 temperatures warm (e.g. Oliver et al., 2018). Increasingly vulnerable populations need more reliable monsoon predictions,  
84 a task complicated by variability across timescales from intraseasonal to interannual, decadal and beyond in a tightly coupled  
85 ocean-atmosphere system (Hazra et al., 2017).

86  
87 The starting point for this synthesis report are the reviews by Schott and McCreary (2001) and Schott et al. (2009), describing  
88 the circulation patterns, air-sea interactions and climate variability on timescales from intraseasonal to interannual, and  
89 relatively large spatial scales. We begin with a description of the large scale setting that has been well established since  
90 Schott et al. (2009) (Section 2). We then consider the structure and propagation of variability in air-sea interactions at  
91 seasonal and intra-seasonal scales, including the contribution of the mesoscale and the ocean's role in air-sea interaction  
92 (Section 3).

93  
94 Section 4 discusses new advances in understanding of the upper ocean circulation, organised by region (southern basin,  
95 equatorial and northern basin). This section includes an update of the near-surface circulation maps of Talley et al. (2011),

96 including recent work on boundary currents around Australia and Madagascar, and a discussion of the biogeochemical  
97 variability observed in each region. The interocean connections with the Pacific, Atlantic and Southern Oceans are discussed  
98 in Section 5. Section 6 describes the variability of the Indian Ocean circulation with the recent advances in understanding  
99 the warming across the basin, climate modes - such as the Indian Ocean Dipole, connection with the El Nino-Southern  
100 Oscillation (ENSO), and Indian ocean marine heatwaves (Section 6.4). Section 7 focuses on multiscale processes in the Bay  
101 of Bengal as an “ocean laboratory”, since there have been multiple international programs in this Bay in the last decade.  
102 Recent advances from the large scales (>100 km) down to sub-mesoscales (100 m to 10 km) and further down to mixing  
103 scales (mm) are discussed. We then link back from mixing to large scales via salinity budgets and coupled phenomena such  
104 as the Madden-Julian Oscillation (MJO) to understand the complexity of these processes across multiple scales. We end  
105 with a short summary and open questions that will need to be addressed over the next decade.

## 106 **2 Large-scale setting**

107 The oceanic and atmospheric circulation of the Indian Ocean are unlike those in the Pacific and Atlantic oceans, largely due  
108 to geography. The Asian landmass limits the northern extent of the Indian Ocean to around 25°N so that there is no high-  
109 latitude cooling of the ocean, and consequently no dense water formation such as that seen in the North Atlantic and, to  
110 some extent, the North Pacific. The intense seasonal variation in temperature over Asia drives the seasonal monsoons: the  
111 southwest monsoon in boreal summer, and northeast monsoon in boreal winter. The timing of the onset of the monsoon, and  
112 associated wet and dry periods in the Indian Ocean rim countries, varies considerably depending on a range of large-scale  
113 climate modes and smaller-scale coupled ocean-atmosphere interactions. The seasonally-reversing winds drive seasonally-  
114 reversing ocean currents in the northern Indian Ocean (Section 4.4), e.g. the southwest/northeast monsoon current and the  
115 Somali Current. Equatorial currents in the Indian Ocean, eastward near the surface above westward undercurrents (Section  
116 4.3), provide rapid connection between the western and eastern basin and are also subject to monsoon dynamics.

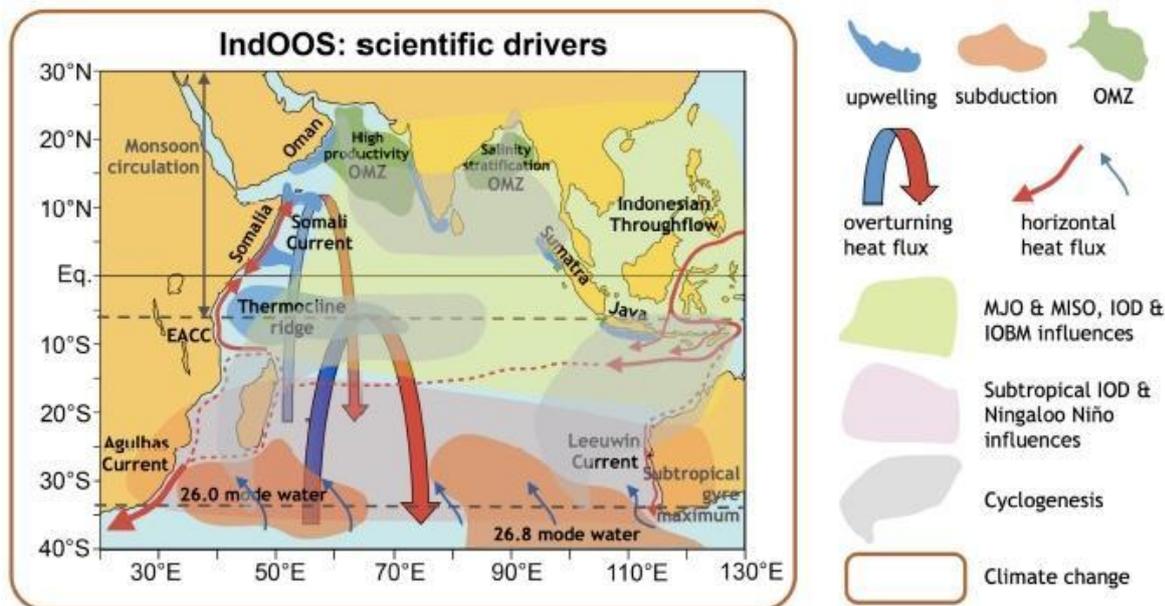

117 In the southern Indian Ocean (Section 4.2), the connection of the Indian and Pacific Oceans through the Indonesian Seas  
118 also contributes to the unique circulation patterns. The very warm and fresh ITF water is funneled into the tropical southern  
119 Indian Ocean and carried westward by the South Equatorial Current. The warm, fresh waters are much lighter than those  
120 further south, creating a north-south density (pressure) gradient that drives near-surface broad, eastward geostrophic currents  
121 between 16°S and 32°S and between Madagascar and Australia (Niiler et al., 2003). This pressure gradient also generates  
122 the Leeuwin Current, a unique poleward-flowing eastern boundary current (Godfrey and Ridgway, 1985) that is a  
123 downwelling region but is also, counter-intuitively, highly productive (Waite et al., 2007). These two features are not found  
124 in the southeastern Atlantic and Pacific oceans. There, the eastern basin currents are characterised by a clear subtropical  
125 gyre circulation with weak, equatorward flow and upwelling against the coast.

126 The tropical Indian Ocean (Section 4.3) is home to the largest fraction of sea surface temperature (SST) warmer than 28°C  
127 (the tropical warm pool), and is therefore a key region for deep atmospheric convection: the upward part of the Walker  
128 Circulation that drives cloud formation and precipitation over the tropical Indo-Pacific. Variation in SST is the primary  
129 driver of variation in exchanges between the ocean and atmosphere and is thus a key focus in this paper. Sea surface salinity  
130 effects on ocean-atmosphere exchanges have become better understood and are discussed throughout and in particular in  
131 Section 7.

132 The tropical Indian Ocean sea surface temperature (SST) has warmed faster over the period 1950–2010 than either the  
133 tropical Pacific or Atlantic (Han et al., 2014). Most of this warming (1.2°C over 1901–2012) has occurred in the western  
134 Indian Ocean, which has been the largest contributor to the overall global SST trend, with implications for primary  
135 productivity (Roxy et al., 2014, 2016). The Indian Ocean accounts for 50-70% of the total anthropogenic warming in the  
136 global upper (700 m) ocean, (Lee et al., 2015; Desbruyères et al., 2017). The deeper ocean (700-2000 m) is warming across  
137 the globe with a robust signature of anthropogenic warming evident even in the short Argo record since 2005 (Wijffels et  
138 al. 2016, Rathore et al. 2020). Warming in the abyss is detectable and widespread, communicated from the surface of the  
139 ocean along pathways from Antarctic Bottom Water formation regions (Purkey and Johnson, 2012). Considerable variability  
140 in the Indian Ocean climate system exists on the backdrop of this strong, long-term warming trend.

141 Variability in the oceanic and atmospheric circulation of the Indian Ocean is the result of complex interactions that are both  
142 internal and external to the Indian Ocean. The recent review of the IndOOS plan (Beal et al., 2020) summarises the major  
143 scientific drivers, of which we still have limited understanding (Fig. 1). Anthropogenic climate change causes a background  
144 trend of ocean warming and increasing acidity due to uptake of heat and carbon dioxide and affects the nature of large and  
145 small scale variability mechanisms.

146

147 **Figure 1: Schematic view of key phenomena in the Indian Ocean (from Hermes et al. 2019). The main scientific**  
 148 **drivers of the Indian Ocean Observing System, including the Oxygen Minimum Zones (OMZs), upwelling and**  
 149 **subduction zones, major heat flux components, the tropical modes of the Madden-Julian Oscillation (MJO), the**  
 150 **Monsoon Intra-Seasonal Oscillation (MISO), the Indian Ocean Dipole (IOD) and Indian Ocean Basin Mode (IOBM),**  
 151 **the subtropical modes of Ningaloo Niño and subtropical IOD, cyclogenesis, and climate change.**

152 A net poleward flow of heat out of the Indian Ocean is accomplished by a combination of the horizontal circulation along  
 153 the boundaries, coupled with the vertical meridional overturning circulation (MOC). The ITF delivers heat from the Pacific  
 154 into the Indian Ocean. The Agulhas Current moves heat rapidly southward at surface and intermediate depths (Bryden and  
 155 Beal, 2001), with 30% of Indian Ocean heat export thought to be carried across 32°S by this gyre circulation (Talley, 2008).  
 156 The shallow Leeuwin Current makes a smaller direct contribution to the poleward flow of heat (Smith et al., 1991; Feng et  
 157 al., 2003; Furue et al., 2017) but generates a rich field of mesoscale eddies that carry heat and momentum into the Indian  
 158 Ocean interior, contributing to heat export across 32°S (Domingues et al. 2006, Feng et al., 2007; Dilmahamod et al. 2018).

159 At intermediate depths (500-2000 m), mode waters of varying density enter the Indian Ocean from the Southern Ocean.  
 160 Along their northward path they mix with lighter waters above, progressively upwelling to the sea surface in a range of  
 161 locations north of 10°S to then return south in a widespread southward Ekman transport of near-surface waters (Schott et  
 162 al., 2009). The lower part of the mode water layer mixes with denser waters below and joins the southward flowing deep  
 163 waters (2000-4000 m). This southward flow also has a contribution from transformed abyssal waters: Antarctic Bottom  
 164 Water moves northward at abyssal depths, mixing with lighter waters above, progressively upwelling along its path from

165 the Southern Ocean to the Indian Ocean to return southward at shallower depths (Talley, 2013). Cross-equatorial flow is  
166 accomplished both at abyssal levels and via the East Africa Coastal Current, seasonally reversing Somali Current and broad  
167 southward flow near the surface (Schott et al. 2009).

168 The remaining elements of Fig. 1 refer to oxygen minimum zones (OMZ) in the Arabian Sea and Bay of Bengal and the  
169 range of mechanisms that drive strong variations in sea surface temperature leading to shifts in atmospheric convection and  
170 precipitation with major effects on rim countries. These mechanisms include: Madden-Julian oscillation (MJO) and  
171 Monsoon Intraseasonal Oscillation (MISO), Indian Ocean Dipole (IOD), Indian Ocean Basin Mode, Subtropical IOD, and  
172 Ningaloo Niño which are discussed further in Section 7. Cyclogenesis is not discussed in this synthesis.

173 Extreme precipitation in the Bay of Bengal and evaporation in the Red Sea and Arabian Sea lead to strong variability in  
174 ocean salinity that in turn impacts ocean circulation and air-sea interaction. The surface salinity gradient in the northern  
175 Indian Ocean decreases from the Arabian Sea in the west to the Bay of Bengal in the east. Strong evaporation over the  
176 Arabian Sea results in highly saline surface waters (Antonov et al., 2010; Chatterjee et al., 2012), while surface waters in the  
177 Bay of Bengal are comparatively fresh and highly stratified as a result of monsoon precipitation and outflow from river  
178 systems such as the Ganges-Brahmaputra (Shetye et al., 1996; Vinayachandran et al., 2002). The surface forcing is balanced  
179 by the seasonally reversing monsoon currents to maintain the climatological distribution of salinity.

### 180 **3 Air-sea interactions**

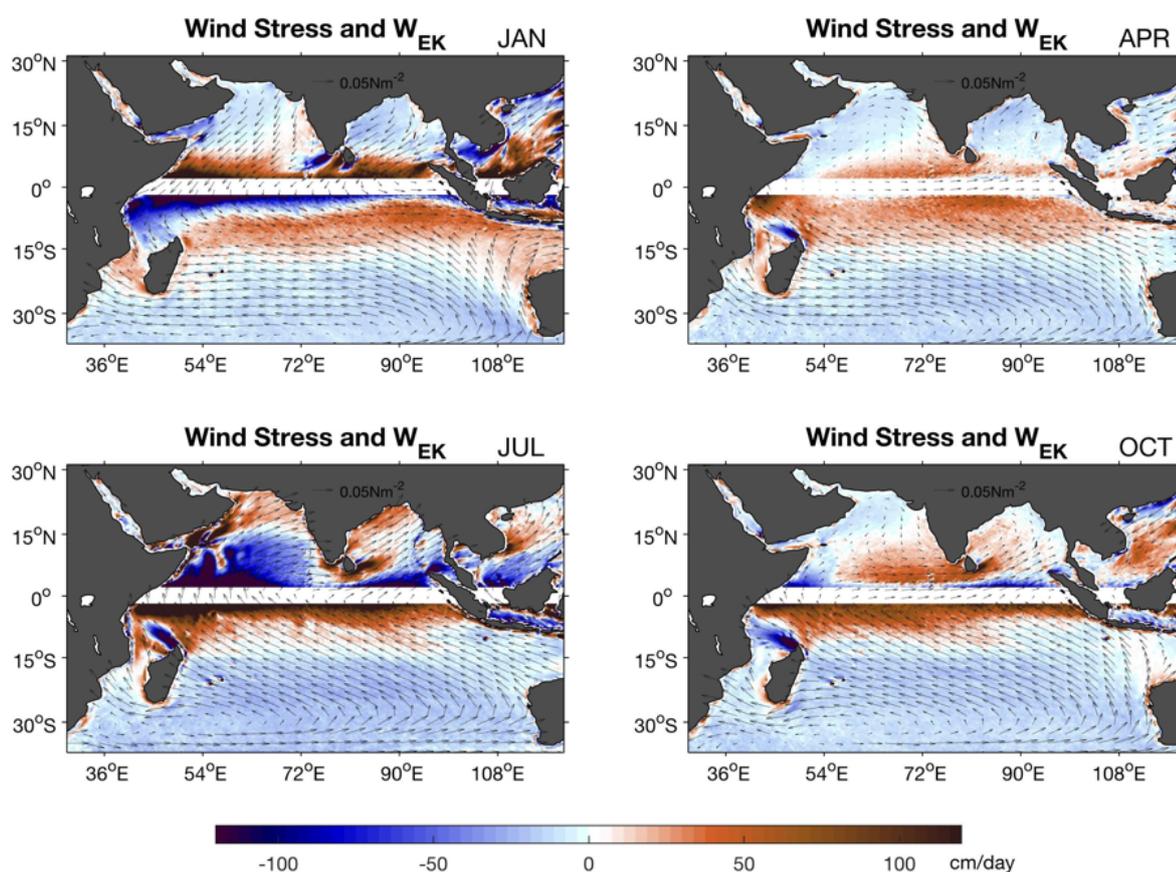

181 The tropical Indian Ocean is highly variable across multiple scales, from intense tropical cyclones to decadal modes of  
182 variability and strong warming due to climate change. Variability at all scales involves a degree of atmosphere-ocean  
183 interaction, such as locally intense heat and moisture fluxes driven by cyclones, large-scale convection in the ascending  
184 branch of the Hadley circulation, and basin scale ocean heat transport carried by overturning cells that contribute to decadal  
185 variability and trends. At intermediate time scales, the intraseasonal oscillations involve strong air-sea coupling (e.g., Demott  
186 et al., 2015). The Indian Ocean Dipole (IOD) is an example of an inherently coupled mode of variability (Saji et al., 1999,  
187 Webster et al. 1999, Murtugudde et al. 2000). The monsoonal rainfall around the Indian Ocean is largely fuelled by warm  
188 SSTs and strong sea-to-air moisture fluxes. These phenomena emphasise the need to understand the mechanisms of air-sea  
189 interaction within the Indian Ocean, with a particular focus on how these processes can be better represented in models to  
190 aid predictions of variability in the Earth system.

#### 191 **3.1 Seasonal cycle and the monsoons**

192 In the open ocean south of 10°S, the wind pattern throughout the year is southeasterly trade winds across the tropics and  
193 subtropics and westerlies south of 35°S (Fig. 2). The evaporative cooling of the ocean surface by the trade winds leads to

194 high salinity throughout the subtropics. The curl of the wind stress drives year-round Ekman pumping (downwelling) south  
195 of around 15°S (Fig. 2). Downwelling of these denser, high salinity surface waters supplies the downward limb of a shallow  
196 overturning circulation (Schott et al., 2002; Schott et al., 2009; Lee 2004). The subsurface path of the shallow overturning  
197 is not well known, and the return to the surface is in any of a number of upwelling zones including the Seychelles-Chagos  
198 Thermocline Ridge, along Somalia and Oman and the west coast of India. North of around 10°S, the winds over the Indian  
199 Ocean are characterised by seasonal reversals due to the monsoons (Fig. 2), which in turn cause most of the near-surface  
200 currents in these regions to seasonally reverse (Schott et al., 2009; Shankar et al., 2002, Section 4.4).

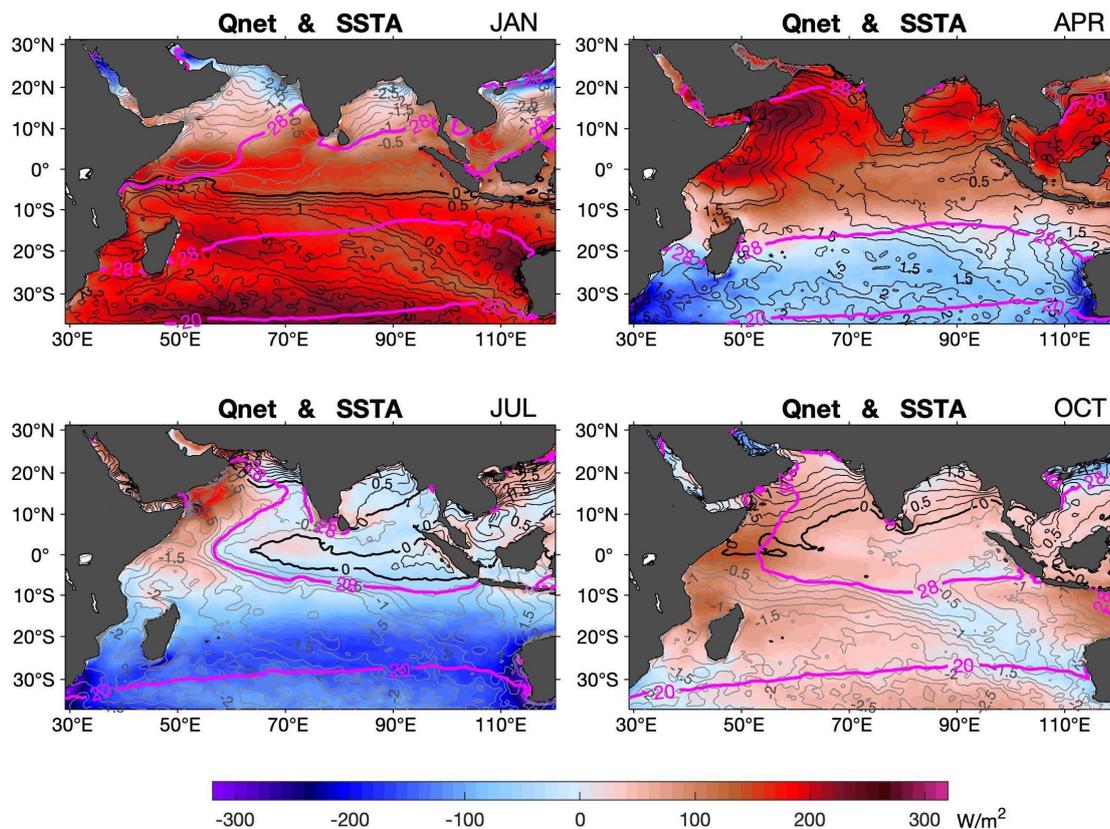

201

202 **Figure 2: Climatology (2001–2018) of monsoon wind stress (vectors) and Ekman pumping rate (colour shaded) with**  
203 **positive values denoting Ekman suction (upwelling) and negative values Ekman pumping (downwelling) for (a)**  
204 **January - NE monsoon, (b) April, (c) July - SW monsoon, and (d) October. The climatology was constructed by the**  
205 **Objectively Analyzed air-sea Flux High-Resolution (OAFlux-HR) analysis (adapted from Yu 2019).**

206 A strong positive correlation between seasonal net heat fluxes into the ocean and SST variability (Fig. 3) suggests that the  
207 seasonal cycle of SST is largely due to the seasonal cycle of winds and cloud cover (Yu et al., 2007). One prominent

208 exception is the Seychelles-Chagos thermocline ridge (located between 5°S and 10°S and east of 50°E), where upwelling  
209 and horizontal advection exhibit substantial seasonal variations that in turn contribute to the seasonal cycle of SST (Hermes  
210 and Reason, 2008; Foltz et al., 2010). On the equator and to the north, seasonally reversing winds drive complex patterns of  
211 upwelling and downwelling that lead to complex SST variability.

212

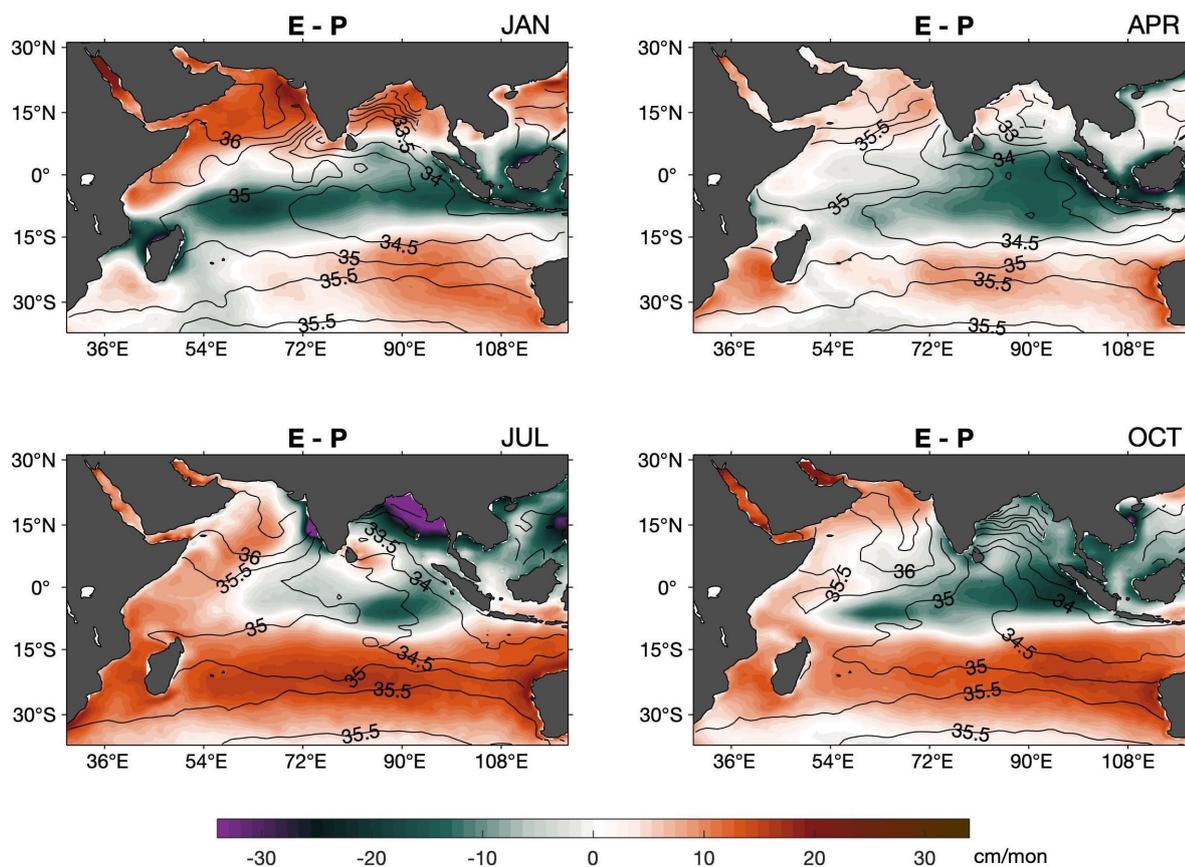

213 **Figure 3: Climatology (2001–2018) of ocean-surface net heat input (colour shaded; positive values denote ocean heat**  
214 **gain and negative values ocean heat loss), SST anomaly (black contours) and 20°C, 28°C SST contours (pink) for (a)**  
215 **January - NE monsoon, (b) April, (c) July - SW monsoon, and (d) October (adapted from Yu 2019). Net heat flux is**  
216 **the sum of solar radiation, longwave radiation, and turbulent latent and sensible heat fluxes. The turbulent heat flux**  
217 **climatology was constructed by the OAF flux-HR analysis and surface radiation climatology by the NASA CERES**  
218 **EBAF (Kato et al., 2013).**

219 In the Bay of Bengal, surface heat fluxes dominate the seasonal cycle of SST, yet subsurface processes including barrier  
220 layers created by the relatively strong salinity stratification compared to the weaker thermal stratification, vertical  
221 entrainment causing warming and cooling of the mixed layer, variations in the depth of penetration of solar radiation and  
222 zonal advection all contribute significantly to SST variability (Thangaprakash et al., 2016). In the Arabian Sea, surface heat

223 fluxes again dominate the variability in SST, with the exception of the upwelling zone along the western boundary  
224 (Chowdary et al., 2015; Yu et al., 2007).

225 The variability in rainfall driven by the monsoons also creates near-surface salinity variability, most notably in the Bay of  
226 Bengal where there is a pronounced annual cycle of sea surface salinity (SSS; Fig. 4, Akhil et al., 2014). Freshwater input  
227 at the northern end of the Bay forms a shallow mixed layer stratified by low salinity and is advected southwards along the  
228 east coast of India, where it is eventually eroded by vertical mixing (Akhil et al., 2014). The variability in freshwater input  
229 contributes to the seasonal cycle of barrier layer thickness in the Bay of Bengal (Howden and Murtugudde, 2001; Thadathil  
230 et al., 2007), which in turn modulates how strongly SST responds to surface forcing (Li et al., 2017). The seasonally  
231 reversing currents that connect the salty Arabian Sea and fresh Bay of Bengal also strongly influence sea surface salinity  
232 patterns (Section 4.1.3).

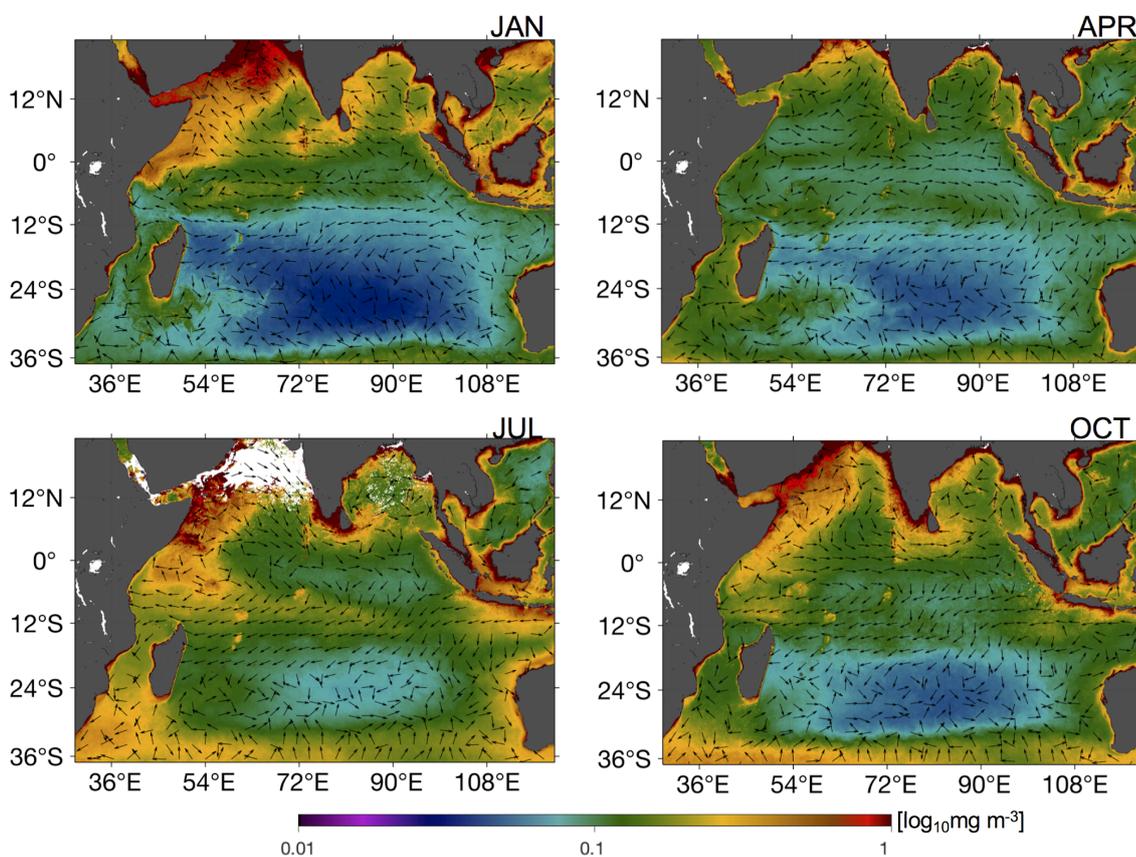

233

234 **Figure 4: Climatology (2001–2018) of evaporation minus precipitation (colour shaded; positive values denote**  
235 **freshwater leaving the ocean and negative values addition of fresh water to the ocean) and sea surface salinity (black**  
236 **contours) for (a) January - NE monsoon, (b) April, (c) July - SW monsoon, and (d) October (adapted from Yu 2019).**

237 The seasonal cycles in the atmosphere and ocean circulation strongly influence the biological productivity of the near-  
238 surface Indian Ocean (Wiggert et al. 2006). Fig. 5 shows the seasonal cycle of satellite chlorophyll *a* and surface currents.  
239 The dramatically low productivity in the subtropics, where wind stress curl drives large-scale downwelling (Fig. 2), and  
240 highly productive coastal boundaries where wind-driven upwelling occurs, highlights the impact of the circulation and  
241 atmosphere-ocean interaction on biological productivity. In turn, the chlorophyll *a* distribution has important implications  
242 for air-sea interaction, since higher concentrations of phytoplankton lead to increased absorption of solar radiation (e.g.,  
243 Morel and Antoine, 1994; Murtugudde et al. 2002). Organisation of chlorophyll *a* at intraseasonal timescales has also been  
244 reported (Section 3.2.1).

245

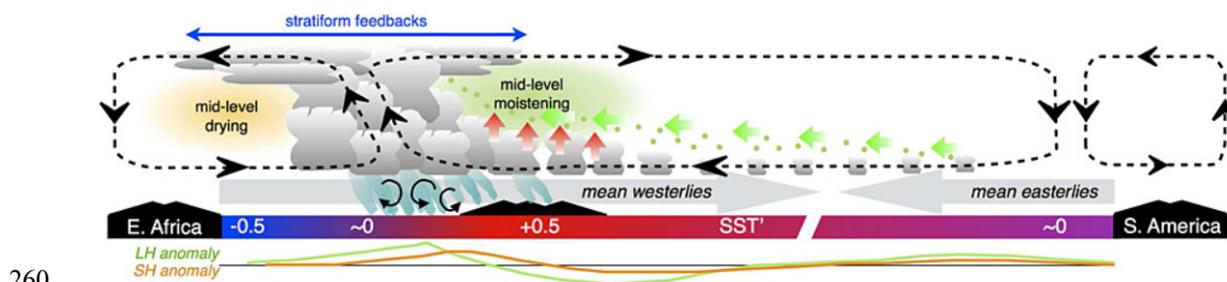

246 **Figure 5: Climatology (2002-2018) of chlorophyll-*a* concentrations (colourmap) and current velocities (arrows) for**  
247 **(a) January (b) April (c) July (d) October. Chlorophyll *a* climatology was obtained from the MODIS-Aqua product**  
248 **and current velocities were obtained from the third-degree Ocean Surface Current Analysis Real-time (OSCAR)**  
249 **product.**

250 **3.2 Intraseasonal air-sea interaction**

251 **3.2.1 Madden-Julian Oscillation - MJO**

252 The Madden-Julian Oscillation (MJO; Madden and Julian, 1972, 1971) is the dominant mode of variability in the Indian  
253 Ocean at subseasonal time scales. The MJO (Fig. 6) is characterised by eastward-propagating features of enhanced and  
254 reduced convection over distances of more than 10,000 km and with a periodicity of around 30–60 days (Zhang, 2005). The  
255 MJO propagates slowly ( $\sim 5 \text{ m s}^{-1}$ ) through the portion of the Indian and Pacific Oceans where the sea surface is warm,  
256 constantly interacting with the underlying ocean and influencing many weather and climate systems. Within the large-scale  
257 envelopes of enhanced convection, smaller-scale clusters of clouds propagate westward, and can produce local extremes in  
258 rainfall. Air-sea interaction is believed to sustain, and perhaps amplify, the patterns of enhanced and reduced convection as  
259 the MJO propagates eastward (Demott et al., 2015).

260

261 **Figure 6: Schematic depiction of Indian and Pacific Ocean feedbacks to the MJO when convection (gray cloud**  
262 **elements) is maximized in the eastern Indian Ocean. Rainfall (aquamarine), circulation anomalies (black dashed**  
263 **cells), convective downdrafts (black rotor arrows), mean winds (faint gray arrows), and moistening by convective**  
264 **detrainment (small green dots) and horizontal and vertical advection (thick green and red arrows, respectively) are**  
265 **overlaid. Net moistening (drying) is shaded green (orange). Positive (red) and negative (blue) SST anomalies for a**  
266 **strong event are shaded, while latent (sensible) heat flux anomalies are shown with green (orange) curves. Central**  
267 **and East Pacific spatial scale is compressed relative to the Warm Pool. Adapted from DeMott et al. (2015).**

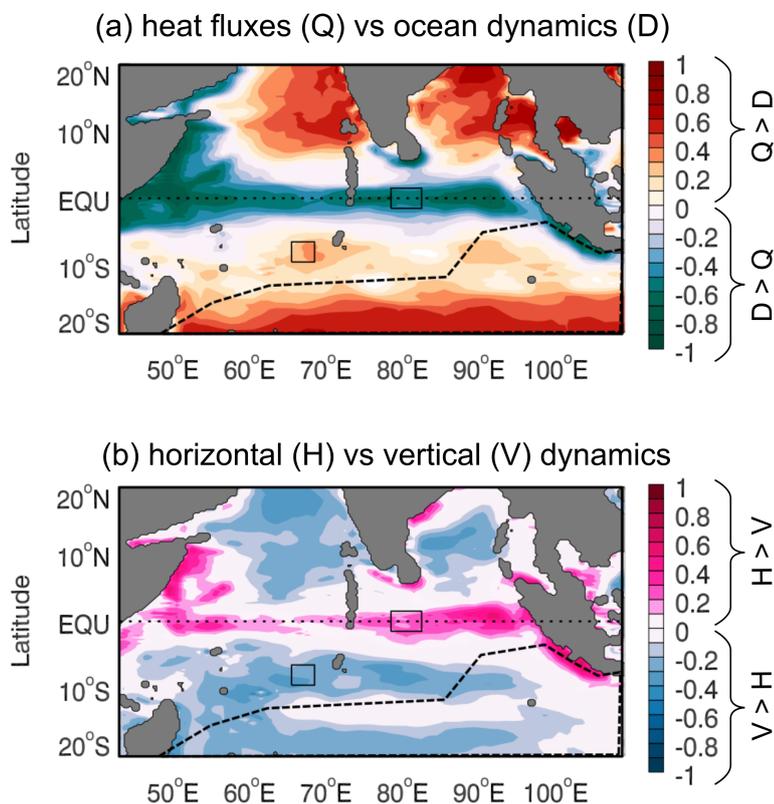

268 The MJO-related pattern of winds results in anomalous westerly (easterly) winds to the west (east) of the region of  
269 convergence, convection and enhanced rainfall (Fig. 6). These winds generate Kelvin and Rossby waves along the Equator.  
270 The Kelvin waves generated by the MJO have been hypothesised (Bergman et al. 2001) to trigger ENSO events in the  
271 Pacific. In the Indian Ocean, there is a distinctive sequence of basin-scale ocean waves generated by the MJO. Eastward-  
272 propagating equatorial ocean Kelvin waves strike the coast of Sumatra, where they generate coastally-trapped Kelvin waves  
273 that propagate northward and southward away from the generation site. Westward-propagating equatorial ocean Rossby  
274 waves are also formed (Oliver and Thompson, 2010; Webber et al., 2010). These waves influence local upwelling and

275 currents; they have been linked to variability in coastal currents around the Bay of Bengal (Vialard et al., 2009), to  
276 enhancement of the spring Wyrtki jets in the eastern equatorial Indian Ocean (Prerna et al., 2019), to changes in subsurface  
277 equatorial currents in the central Indian Ocean (Iskandar and McPhaden, 2011) and to changes in upwelling and chlorophyll  
278 a concentration in the off-equatorial central Indian Ocean (Webber et al., 2014). Downwelling Rossby waves in the western  
279 Indian Ocean create positive SST anomalies through a combination of reduced entrainment of cooler water from below and  
280 zonal advection (Rydbeck et al., 2017; Webber et al., 2012b). These waves therefore act as a triggering mechanism for new  
281 MJO events (Rydbeck and Jensen, 2017; Webber et al., 2010, 2012b, 2012a), and may also play a role in amplifying existing  
282 MJO events.

283 MJO-related winds also lead to variability in mixing within and at the bottom of the mixed layer. Westerly wind bursts  
284 generate zonal currents that create strong vertical current shear (Moum et al., 2014). These currents and the associated  
285 mixing persist after the passage of the atmospheric disturbance. Cooler waters from below the surface are mixed with surface  
286 waters, leading to a reduction in available ocean heat content for the next MJO event and thus reducing its potential  
287 amplitude (Moum et al., 2016). By examining the causes of SST variability in two separate MJO events, McPhaden and  
288 Foltz (2013) showed that the presence or absence of barrier layers may play a crucial role in determining how strongly  
289 mixing and vertical entrainment influence SST. They also found that zonal advection plays a relatively stronger role when  
290 a barrier layer is present. Chi et al. (2014) confirmed the importance of barrier layers in influencing the turbulent heat flux,  
291 but found that thin barrier layers can be eroded by strong current shear that occurs during active phases of the MJO. Wind  
292 mixing and surface heat and freshwater fluxes both contribute in roughly equal proportions to intraseasonal variability in  
293 mixed layer depth (Keerthi et al., 2016).

294 Various studies have investigated the relative importance of surface heat fluxes and subsurface ocean processes for the  
295 evolution of SST at intraseasonal time scales. Several observational studies have concluded that the SST variability is  
296 predominantly generated by variability in surface heat fluxes in the Seychelles-Chagos Thermocline Ridge (SCTR,  
297 Jayakumar et al., 2011; Vialard et al., 2008), while Drushka et al. (2012) suggest this finding applies across most of the  
298 tropical Indian Ocean. Such studies, however, typically exhibit large uncertainty in the subsurface ocean terms. Modelling  
299 studies have shown that ocean dynamics play an important role in generating SST variability (Halkides et al., 2015; Han et  
300 al., 2007). For example, Fig. 7 from the study of Halkides et al. (2015) shows the relative contribution of modelled ocean  
301 dynamical processes and thermodynamical processes (i.e., surface heat fluxes) in forcing intraseasonal SST variability. Fig.  
302 7a shows that ocean dynamical processes (green shading), including horizontal and vertical advection, are the dominant  
303 source of intraseasonal SST variability on the equator and in upwelling regions off Indonesia, Sri Lanka and along the  
304 western boundary. The ocean dynamical processes are in turn dominated by horizontal advection along the equator and  
305 tropical coastlines (Fig. 7b, pink shading), and vertical advection (blue shading) in the off-equatorial ocean interior.

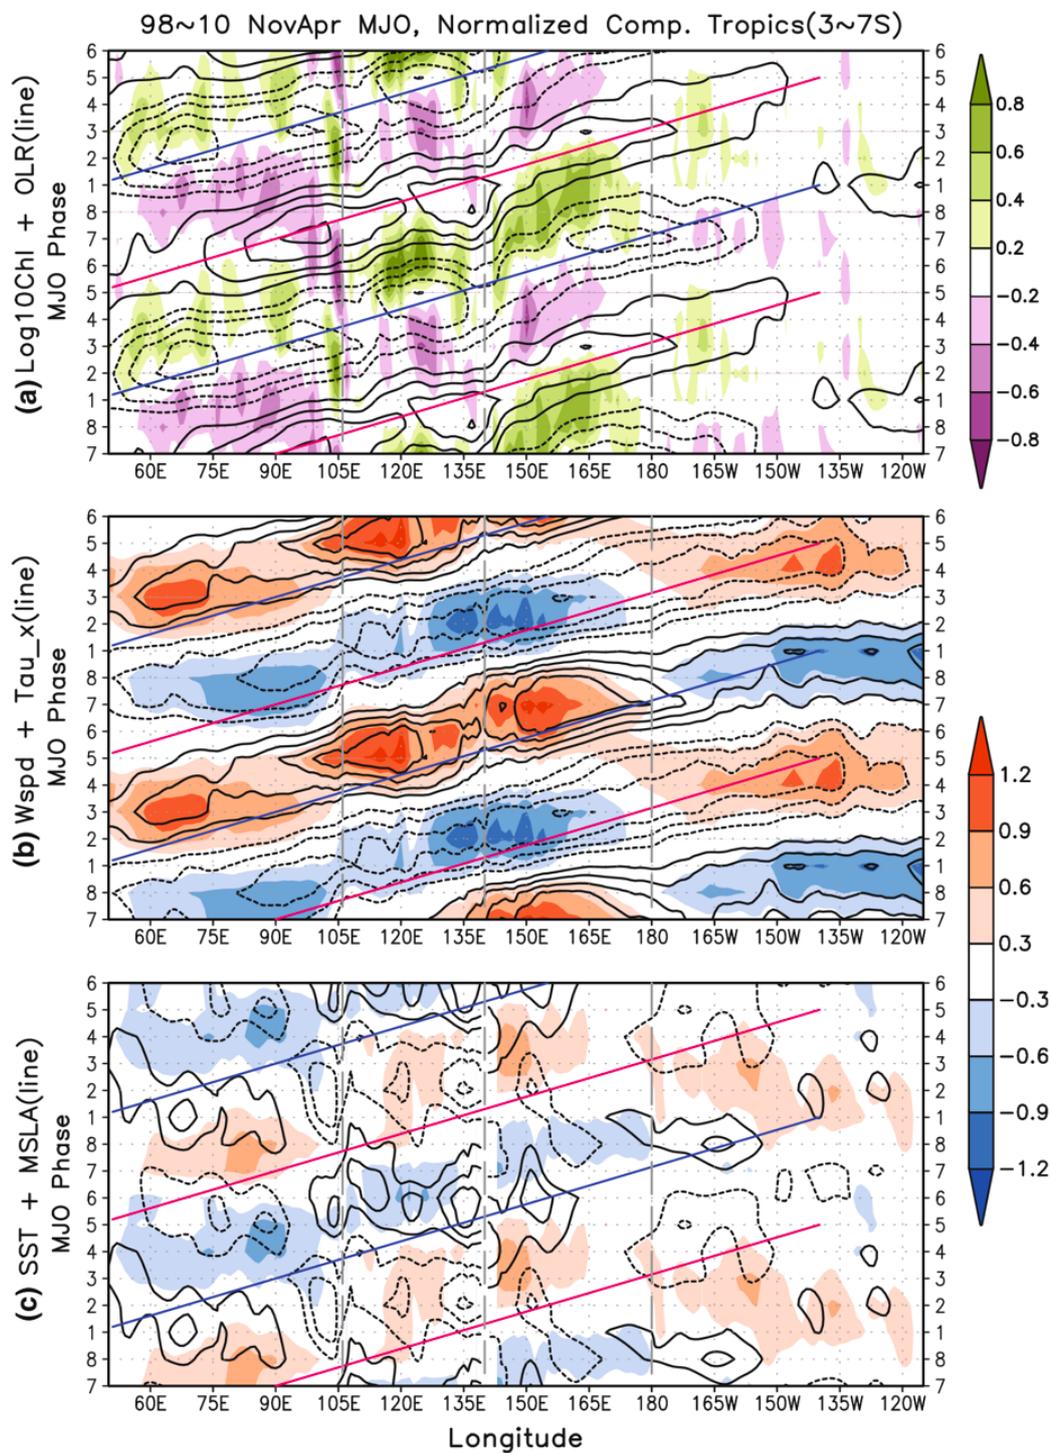

306

307 **Figure 7: Modelled balance of processes driving intraseasonal SST variability ( $M_B$ ). (a) Relative role of heat fluxes**  
308 **(Q) and ocean dynamics (D) in driving SST variability, with red (green) colours implying Q (D) dominates forcing,**  
309 **(b) Relative role of horizontal (H) and vertical (V) processes in the dynamical forcing, with pink (blue) colours**  
310 **implying that H (V) processes dominate. All fields are derived from the ECCO-JPL ocean state estimate. The dotted**  
311 **line marks the Equator, dashed line in the southern hemisphere outlines a region in which the model does not fully**  
312 **resolve the ocean heat budget, and the boxes on the Equator and at 10°S mark regions for further analysis not**  
313 **described here. Modified from Halkides et al. (2015).**

314 Organisation of chlorophyll a at intraseasonal timescales has also been reported, with model studies indicating potential  
315 biophysical feedbacks due to the variability of penetrative radiation into the water column (Waliser et al. 2005, Jin et al.  
316 2013a). In the Bay of Bengal, the proportion of incoming solar radiation absorbed within the mixed layer varies between  
317 60% and 97% due to a combination of variability in chlorophyll a concentration and mixed layer depth (Lotliker et al.,  
318 2016). Representing the seasonal cycle of chlorophyll a concentration in the Arabian Sea in a coupled model led to  
319 substantial changes in the simulated SST and monsoon rainfall over India (Turner et al., 2012), suggesting that incorporating  
320 this process into coupled models may be important to improve simulation of monsoon rainfall and circulation around the  
321 Indian Ocean.

322 Figure 8 illustrates propagation of surface patterns in an MJO composite constructed by Jin et al. (2013a). In each panel the  
323 peak in outgoing longwave radiation (OLR, a proxy for convection) is indicated by a red diagonal line. The MJO generates  
324 substantial surface heat flux anomalies that create a pattern of surface heat fluxes and SST anomalies such that warm (cool)  
325 SSTs lead enhanced (reduced) convection by a quarter of a phase (e.g., Shinoda et al., 1998). The MJO also leads to low-  
326 frequency rectifications in the mean state of physical and ecosystem responses (Fig. 8, Waliser et al. 2003, Jin et al. 2013a,b).

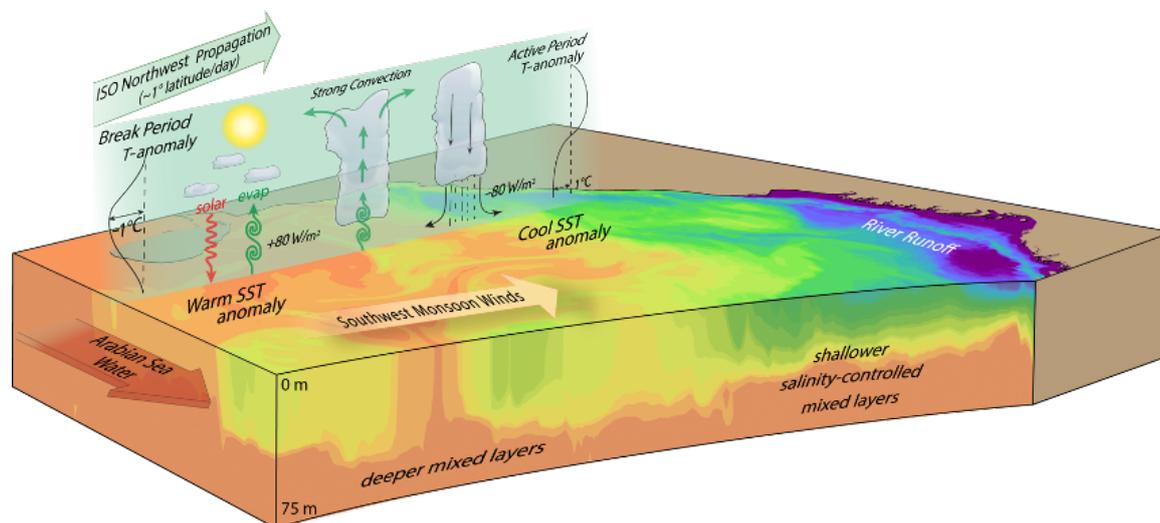

328 **Figure 8: MJO composite evolution for the Boreal winter (Nov-Apr) averaged over latitudes 3°–7°S for the period of**  
329 **November 1st, 1997 to October 31st, 2010, of a)  $\text{Log}_{10}\text{Chl}$  from SeaWIFS satellite observations (shaded) and satellite-**  
330 **derived outgoing longwave radiation (contour), b) wind speed (shaded) and zonal wind stress (contour), both from**  
331 **the cross-calibrated multi-platform (CCMP) dataset, and c) NOAA-OI satellite SST anomalies (shaded) and AVISO**  
332 **mean sea level anomaly (contour). All contour intervals match shading levels in (c), and solid (dash) line indicates**  
333 **positive (negative) values. All variables are normalised, and the same MJO composite is repeated for two cycles for**  
334 **convenience. There are between 127–227 events composited for each MJO phase. Red diagonal lines indicate peak**  
335 **signals of positive OLR, and blue lines indicate negative OLR peak, so these are guides for the MJO propagation.**  
336 **The relative location of each propagation line in all panels is the same. Left and center gray vertical dashed line**  
337 **indicates west and east boundary of the Maritime Continent, and the right gray line is on the Dateline, where Chl a**  
338 **propagation stops. From Jin et al. (2013a).**

### 339 3.2.2 Monsoon Intraseasonal Oscillation - MISO

340 While the MJO dominates intraseasonal variability during October to April, during May to September (boreal summer,  
341 southwest monsoon), the Monsoon Intraseasonal Oscillation (MISO; Goswami, 2012; Suhas et al., 2013) dominates. MISOs  
342 can be seen as low pressure systems laden with moisture which deliver rain from atmospheric instabilities (Fig. 9). The  
343 MISO is also known as the Boreal Summer Intraseasonal Oscillation (BSISO; Lau and Waliser, 2012; Lee et al., 2013). The  
344 MISO oscillations are dynamically linked to the equatorial MJO (e.g., Sperber and Annamalai, 2008), but exhibit  
345 northeastward and northwestward propagating features, with the main centre of action being the Bay of Bengal. These  
346 northward-propagating bands of enhanced and reduced rainfall exhibit a similar relationship with SST to the MJO: warm  
347 SST leading increased rainfall (cool SST leading reduced rainfall) that then determine the wet/dry (or active/break) cycles  
348 of the South Asian monsoon (Vecchi and Harrison, 2002; Roxy et al., 2013; Suhas et al., 2013; Zhang et al., 2018). These  
349 SST anomalies are primarily forced by variations in surface heat fluxes in the Bay of Bengal (Girishkumar et al., 2017;  
350 Vialard et al., 2012), while variations in wind-induced mixing, Ekman pumping and entrainment drive SST variability in  
351 the Arabian Sea (Duncan and Han, 2012; Vialard et al., 2012).

352

353 **Figure 9: A schematic of the Monsoon Intraseasonal Oscillation (MISO) in the Bay of Bengal, showing the coupled**  
354 **ocean-atmosphere 30–60 day mode northwestward propagation and associated processes in the atmosphere and the**  
355 **ocean. (From Mahadevan et al., 2016a).**

356 Simulations of the MISO are still generally poor in state-of-the-art coupled models (e.g., Goswami et al., 2013; Jayakumar  
357 et al., 2017; Sabeerali et al., 2013; Sharmila et al., 2013) and re-analysis products (e.g. Sanchez-Franks et al., 2018).  
358 Evidence exists from observations of low-level convergence and OLR, as well as forced atmospheric and coupled ocean-  
359 atmospheric model experiments, that both MJOs and MISOs are phenomena that require coupling between the ocean and  
360 atmosphere to exist. This is even though the scales of SST anomalies tend to be an order of magnitude smaller than the  
361 scales of the propagating atmospheric systems (Waliser et al., 1999; Zhou and Murtugudde, 2009). Including air-sea  
362 coupling in simulations of the MISO has been identified as key to improving simulation of this oscillation in some models  
363 (e.g., Jayakumar et al., 2017; Li et al., 2018; Roxy et al., 2013; Sharmila et al., 2013), and has been shown to improve aspects  
364 of simulation in others (e.g., Bellon et al., 2008; Peatman and Klingaman, 2018).

365 While new theories continue to be proposed for MJOs (e.g., Wang et al., 2016), MISOs have not received similar attention  
366 likely due to their more local nature compared to the global impacts of MJOs (e.g. their impact on ENSO). The mechanism  
367 that causes the northward propagation of the MISO is still a topic of research. The most recent theory for MISOs proposed  
368 by Zhou et al. (2017a, b) invokes an explicit coupling between the ocean and the atmosphere in a so-called Central Indian  
369 Ocean (CIO) mode. Zonal winds at intraseasonal timescales over the Indian Ocean are argued to be coupled to SSTs to  
370 produce a barotropic instability in the meridional gradient of the zonal winds. The horizontal atmospheric eddy fluxes  
371 generated by the barotropic instability are argued to explain the northward propagation and the advection of momentum and  
372 moisture as a coupled phenomenon. Key questions remain about the oceanic and air-sea interaction processes that reorganise

373 the SSTs in the CIO mode as well as the role of the vertical vs. horizontal shears in driving northward propagation of  
374 MISOs.

375 Observations and models indicate that MISOs may be slowing down because of the warming in the Indian Ocean (Sabeerali  
376 et al., 2013), which needs to be understood better for providing reliable monsoon predictions and projections in this climate  
377 vulnerable region. This is underscored by the observational evidence that climate variability and change are increasing the  
378 frequency of dry spells and the intensity of wet spells in the Indian summer monsoon, which are directly related to MISO  
379 (Singh et al., 2014).

### 380 **3.2.3 Intraseasonal drivers of heavy rainfall**

381 As the MJO season begins to wind down in April, northward propagating MISOs begin to become dominant in the northern  
382 Indian Ocean, north of around 5°N. While the southwesterlies produce some of the strongest coastal upwelling off Somalia  
383 and cool the Arabian Sea, the Bay of Bengal remains warm and largely above the convective threshold (28°C) thanks to the  
384 freshwater input from rainfall as well as rivers discharging into the Bay (Roxy and Tanimoto, 2007). The freshwater input  
385 creates a shallow density stratification (barrier layer) within the temperature mixed layer and thereby weakens the upwelling  
386 of cold water from the thermocline. MISOs deliver rain from atmospheric instabilities, but what controls the rainfall at  
387 intraseasonal timescales during the summer can be expected to be region specific with moisture supply determining the  
388 rainfall variability over land (Pathak et al., 2017).

389 Over the ocean, the largely evaporative Arabian Sea is relatively cool but the southwesterlies begin to slow down as they  
390 approach the Western Ghats mountain range on the west coast of India, leading to maximum rainfall there during the boreal  
391 summer monsoon season (Xi et al., 2015). Rather counterintuitively, the warm SST in the Bay of Bengal remains above the  
392 convective threshold (Gadgil et al., 1984; Roxy, 2013) and yet, the ocean is not in direct control of the intraseasonal rainfall  
393 events. Once the SSTs are organised to be warm enough to support atmospheric convection, baroclinic instabilities, and not  
394 static instabilities induced by warm SSTs, drive the majority of rainfall over the Bay of Bengal (Xi et al., 2015). These  
395 findings should provide a proper paradigm for understanding the role of SST in monsoon and MISO in terms of the ocean  
396 dynamics and air-sea interaction processes that matter most.

### 397 **3.3 Ocean internal variability impacts on air-sea interaction**

398 Mesoscale eddies are ubiquitous in the world ocean. In the Pacific and Atlantic, the tropical instability waves are known to  
399 have air-sea coupling and to impact on low frequency variability such as ENSO (Jochum et al., 2004; Jochum and  
400 Murtugudde, 2004; An, 2008). The tropical Indian Ocean is, however, dominated by linear dynamics and the impacts of  
401 eddies are (or seem) small. Even though the Indian Ocean has the largest SST variability occurring at seasonal timescales,  
402 strong mesoscale variability is also observed along the Somali coast where the western boundary current crosses the Equator.

403 The slope of the East African coastline and the equatorial crossing of the low-latitude jet produce multiple eddies (Nof and  
404 Olson, 1993), which are shown to generate strong air-sea coupling at mesoscales (Schott and McCreary, 2001; Schott et al.,  
405 2009; Vecchi et al., 2004; Seo et al., 2008). Some intraseasonal oscillations in the ocean were reported in the southwestern  
406 tropical Indian Ocean (Kindle and Thompson, 1989) but generally, the impact of ocean internal variability on SSTs in the  
407 tropics has not been widely studied.

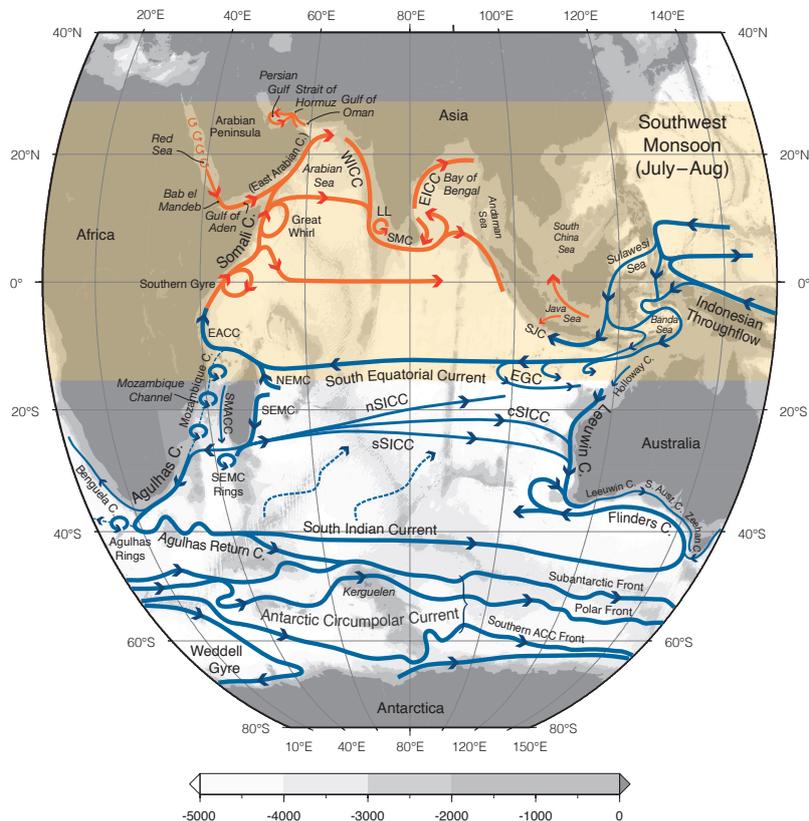

408 Low-frequency internal variability is also possible. Jochum and Murtugudde (2004) performed forced ocean model  
409 experiments with climatological forcing alone to demonstrate that significant low-frequency variability at interannual  
410 timescales is generated in the Indian Ocean due internal variability such as mesoscale eddies and other types of nonlinearity.  
411 The role of internal variability in regional coupled climate variability as well as ecosystem and biogeochemistry remain  
412 interesting problems for this already warm ocean, which is continuing to warm rapidly and monotonically. In this warm  
413 ocean, even small SST anomalies can be important for generating large-scale ocean atmosphere interactions (Palmer and  
414 Mansfield, 1994).

## 415 **4 Upper Ocean Circulation and Biogeochemical Variability**

### 416 **4.1 Overview**

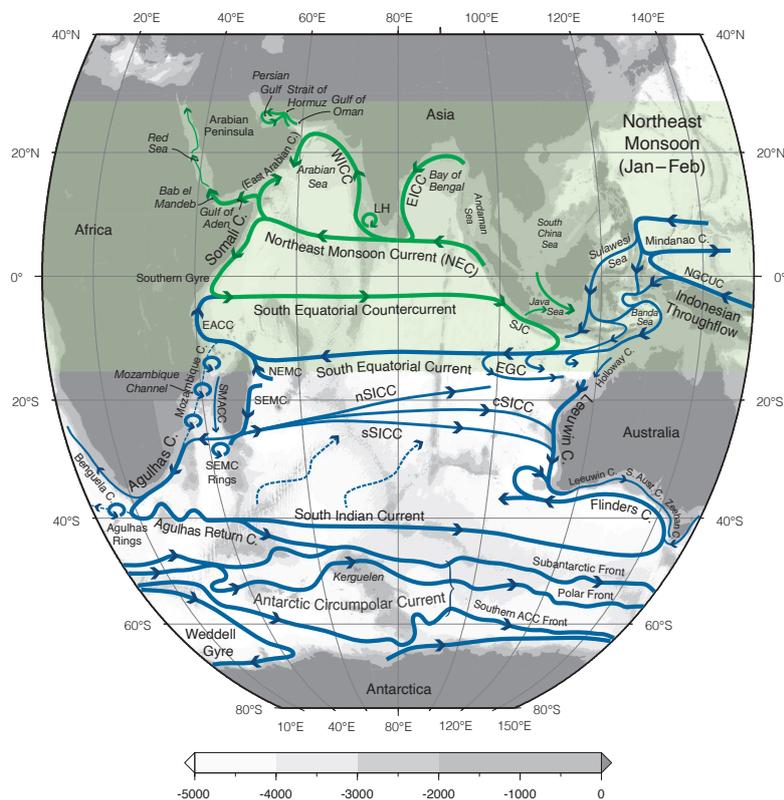

417 The near surface circulation in the Indian Ocean consists of the monsoon-dominated, seasonally reversing currents north of  
418 around 10°S, and the steady currents to the south, as illustrated in Fig. 10a for the southwest monsoon (July-August) and  
419 Fig. 10b for the northeast monsoon (January-February). This figure has been updated from Talley et al. (2011) to recognise  
420 recent advances in understanding of circulation patterns. In the northern Indian Ocean, additions are a revision of the Red  
421 Sea circulation (Menezes et al., 2019). In the southern Indian Ocean, moving in an anti-clockwise direction from the  
422 Maritime Continent, additions are: 1) seasonally reversing flows in the Java Sea; 2) the Holloway Current along Australia's  
423 Northwest Shelf (Holloway and Nye, 1985; Holloway, 1995; Brahmanpour et al., 2016); 3) revised position of the the  
424 salinity-driven Eastern Gyral Current that flows eastward from around 90°E along approximately 15°S, recirculating  
425 Indonesian Throughflow Water from the South Equatorial Current to supply the poleward-flowing Leeuwin Current (Meyers  
426 et al., 1995; Domingues et al., 2007; Menezes et al., 2013, 2014); 4) the South Indian Countercurrent with 3 distinct branches,  
427 northern, central and southern, flowing from the southern tip of Madagascar to Australia where they merge with the  
428 poleward-flowing Leeuwin Current (Menezes et al., 2014); and 5) the splitting of the Flinders Current near 110°E, with  
429 one branch recirculating back toward Australia, and the other a westward continuation of the Flinders Current, previously  
430 not shown (Duran et al., 2020).

431

432

433 **Figure 10a: Schematic near-surface circulation during the Southwest Monsoon (July-August). Blue: year-round**  
434 **mean flows with no seasonal reversals. Orange: monsoonally reversing circulation (after Schott & McCreary, 2001).**

441 **bathymetry.**

442

443 **Figure 10b: Schematic near-surface circulation during the Northeast Monsoon (January-February). Details as for**  
444 **Fig. 10a.**

445 The intermediate and deep circulation of the Indian Ocean, and overturning cells will not be examined in this synthesis. The  
446 reader is referred to Talley et al. (2011) and references therein.

447

## 448 4.2 Southern Indian Ocean

### 449 4.2.1 South Equatorial Current

#### 450 4.2.1.1 Circulation

451 The South Equatorial Current (SEC) carries Indonesian Throughflow (ITF) waters into the interior Indian Ocean, flowing  
452 westward between 10–20°S (Fig. 10a and 10b). Upon reaching the northern tip of eastern Madagascar, it bifurcates and  
453 supplies the Northeast Madagascar Current (NEMC; Schott and McCreary, 2001; Song et al., 2004; Valsala and Ikeda,

454 2007) and the Southeast Madagascar Current (SEMC) and contributes to the development of Mozambique Channel eddies.  
455 The mean flow through the Mozambique Channel is weak (Song et al., 2004), although there is an indication from ocean  
456 model results that the eddy-dominated flow contributes on the order of 20Sv southward (Durgadoo et al., 2013). The  
457 Mozambique Channel eddies, eddies from the SEMC and recirculation combine to feed into the Agulhas Current (Schott  
458 and McCreary, 2001).

459  
460 The SEC experiences intraseasonal, seasonal and interannual variability. In the eastern IO, the intraseasonal variation of the  
461 SEC is mostly attributed to the baroclinic instability of the mean current (Feng and Wijffels, 2002), which is important for  
462 the meridional heat transport in the region and contributes to the demise of Indian Ocean Dipole events (Ogata and  
463 Masumoto, 2011; Yang et al. 2015). Barotropic instability of the SEC has also been proposed to be a key mechanism for  
464 generating intraseasonal variability (Yu and Potemra, 2006). These intraseasonal signals propagate westward as Rossby  
465 Waves, influencing the SEC variability in the western Indian Ocean (Zhou and Murtugudde, 2008).

466  
467 Interannual variability of the SEC in the eastern Indian Ocean conveys the ENSO and IOD influences on the ITF transport  
468 variability into the western Indian Ocean. Geostrophic transport variability in the long-time repeat XBT line IX1 (Liu et al.,  
469 2015) shows that the SEC is stronger during La Niña and Indian Ocean Dipole events.

470 The SEC also conveys the Pacific Decadal Oscillation influences on the ITF on decadal time scales (Section 6.1.2). During  
471 the climate change hiatus period of 2000-2011, the enhanced heat transport of the SEC/ITF was a key mechanism for the  
472 fast warming trend in the southern subtropical Indian Ocean (Section 6.1).

473

#### 474 **4.2.1.2 Biogeochemical Variability**

475 The ITF impacts both ocean currents and basin-scale biogeochemistry (Talley and Sprintall, 2005; George et al., 2013; van  
476 Sebille et al., 2014). Talley and Sprintall (2005) mapped silicate on the 31.96 potential density surface, revealing a striking  
477 silicate maximum associated with the SEC that extends westward to at least 60°E, highlighting the broad reach of ITF  
478 nutrient influence into the Indian Ocean. Ayers et al. (2014) estimated the depth- and time-resolved nitrate, phosphate, and  
479 silicate fluxes at the three main exit passages of the ITF that feed into the SEC: Lombok Strait, Ombai Strait, and Timor  
480 Passage. They found that the nutrient flux is significant relative to basin wide new production, and that the majority of ITF  
481 nutrient supply to the Indian Ocean via the SEC is to thermocline waters, where it is likely to support primary production  
482 and significantly impact biogeochemical cycling.

483

484 Satellite chlorophyll and primary production estimates suggest that values in the SEC are considerably higher than those  
485 found in the southern hemisphere subtropical gyre to the south, with Chla from ~0.10 to 1.0 mg/m<sup>3</sup> and primary production

486 from ~400 to 1000 mgC m<sup>-2</sup> d<sup>-1</sup> (Fig. 5 and see Figs. 5 and 6 in Hood et al., 2017) The highest concentrations and rates in  
487 the SEC are observed in the Eastern Indian Ocean in July and August during austral winter, associated with the  
488 aforementioned ITF nutrient sources and upwelling off Java. The lowest chlorophyll concentrations and rates are observed  
489 in January (austral summer).

490

491 Between 50 and 80°E the SEC is coincident with the southern half of the Seychelles-Chagos Thermocline Ridge (SCTR,  
492 Vialard et al., 2009). The SCTR is characterized by a relatively shallow thermocline and thin mixed layer (~30m) across  
493 the south tropical Indian Ocean in the latitude band 5-15°S. Between 50 and 80°E the SCTR/SEC is a region of significant  
494 upwelling (Hermes and Reason, 2008; Vialard et al., 2009; Resplandy et al., 2009; Dilmahamod, 2014), which affects  
495 biogeochemistry, and even fisheries (Resplandy et al., 2009; Robinson et al., 2010; Dilmahamod, 2014). Model results and  
496 satellite observations show that the SEC/SCTR region exhibits an annual cycle in surface chl<sub>a</sub> concentration and primary  
497 production, with the highest values in austral winter (June-August; > 0.20 mg/m<sup>3</sup> and >600 mgC m<sup>-2</sup> d<sup>-1</sup>, respectively) due  
498 to the strong southeasterly winds that increase wind stirring and induce upwelling (Resplandy et al., 2009; Dilmahamod,  
499 2014; Fig. 5 ; see also Figs. 5 and 6 in Hood et al., 2017).

500

501 Vertical sections of the SEC/SCTR region also reveal a deep chl<sub>a</sub> maximum (George et al., 2013). Along 65°E this  
502 maximum shoals from > 100 m at 16°S to ~50 m at 10°S due to upwelling. Vertical sections of the SCTR also show that the  
503 increases in surface Chl-a concentrations in austral winter are associated with decreases in the subsurface chl<sub>a</sub> maximum  
504 (Resplandy et al., 2009; Dilmahamod, 2014). Surface freshening associated with the core of the SEC also influences the  
505 chl<sub>a</sub> distribution in the SCTR region by modulating the static stability and mixed layer depth (George et al. (2013).

506

507 The SEC provides relatively oligotrophic (low nutrient, low chlorophyll and low primary production) tropical source waters  
508 that feed into the EACC, NEMC, SEMC and the Mozambique channel.

## 509 4.2.2 Western Boundary

### 510 4.2.2.1 Circulation

511 The Agulhas Current (Fig. 10) has long been known as one of the strongest western boundary currents in the global oceans,  
512 with an average transport of 70 Sverdrups and current speeds in excess of 2 m s<sup>-1</sup> (Beal et al., 2011). The Agulhas Current  
513 plays a vital role in the global thermohaline circulation, advecting warm, salty, subtropical water southwards, following the  
514 continental shelf of South Africa and meandering less than 150 km offshore (Gründlingh, 1983; Lutjeharms 2006). The  
515 strength and warmth of the Agulhas Current influences atmospheric storm tracks and storm development. The large moisture  
516 source of the warm Agulhas Current region contributes significantly to the frequency and strength of African precipitation,  
517 which significantly impacts rain-fed subsistence farming (Hermes et al. 2019 and references therein).

518  
519 South of the tip of Africa, the Agulhas Current retroflects eastwards into the South Indian Ocean (Fig. 10). This retroflexion  
520 area is highly variable, occluding rings that propagate into the South Atlantic Ocean. The Agulhas variability is linked  
521 upstream to the IOD, SIOD and ENSO and downstream with the Atlantic meridional overturning circulation, providing an  
522 essential link between the Pacific, Indian and Atlantic Oceans. Estimates of the rate of mass and heat exchange carried by  
523 Agulhas leakage south of Africa (and the number of rings shed per year) vary and are difficult to verify reliably (Weijer et  
524 al., 2014). Temporal variations in the Agulhas Current have been shown to have a significant effect on inter-ocean exchange  
525 between the South Indian and South Atlantic oceans, primarily by influencing the frequency of ring shedding at the Agulhas  
526 retroflexion (van Sebille et al., 2011; le Bars et al., 2014). Seasonal changes in the Agulhas retroflexion region (Lutjeharms  
527 and van Ballegooyen, 1988; Quartly and Srokosz, 1993) and in the southwest Indian Ocean (Ffield et al., 1997) have been  
528 suggested from hydrographic and satellite data (Krug et al., 2012), but with weak statistical significance due to a lack of  
529 sufficiently long time series.

530  
531 Although long term observations in this region are limited there are numerous recent studies that have further elucidated our  
532 understanding of the Agulhas Current. Beal and Elipot (2016) used 3 years of in situ data to show that, contrary to  
533 expectations, the Agulhas Current has not intensified since the early 1990s. Instead, it has broadened as a result of more  
534 eddy activity, driven by intensifying winds. Variability in the path and strength of the Agulhas Current has mostly been  
535 attributed to solitary Agulhas meanders within the Current system (also known as Natal pulses) which drive upwelling and  
536 cross-shelf transports, affecting marine productivity, fisheries and recruitment over the Agulhas Bank (Beal and Bryden,  
537 1999; Roberts et al., 2010, Elipot and Beal, 2015). Recent work has highlighted the importance of submesoscale eddies in  
538 the AC frontal region driving an inshore edge flow reversal which can have important consequences on fisheries (Krug et  
539 al., 2017).

540  
541 The advance in models has also helped improve our understanding of the Agulhas Current, which is generally not well  
542 represented in global ocean models. Hutchinson et al. (2018) used idealized models to expose a link between the seasonality  
543 of the Agulhas Current and propagation of first baroclinic mode Rossby waves communicating the wind stress signal across  
544 the western portion of the Southern Indian Ocean, with the signal from winds further east having little effect.

#### 545 4.2.2.2 Biogeochemical Variability

546 Chlorophyll *a* concentrations and production rates in Mozambique Channel surface waters are generally low ( $< 0.4 \text{ mg/m}^3$   
547 and  $< 700 \text{ gC m}^{-2} \text{ d}^{-1}$ , Fig. 5), and not significantly different in cyclonic and anticyclonic eddies (Lamont et al., 2014; Barlow  
548 et al., 2014; see also Figs. 5, 6 and 20 in Hood et al., 2017). Deep chlorophyll maxima are also observed between 25 and  
549 125 m depth depending on the proximity to the shelf and the influence of mesoscale eddies (Barlow et al., 2014; Lamont et

550 al., 2014). Eddies in the Mozambique Channel also have a strong influence on the lateral transport of nutrients and  
551 chlorophyll from the coasts of Madagascar and Africa. Indeed, enhanced phytoplankton production within both cyclonic  
552 and anticyclonic eddies in the Mozambique Channel often occurs in response to lateral nutrient inputs into the euphotic zone  
553 by horizontal advection from the coasts of Madagascar and Africa rather than eddy induced upwelling and downwelling  
554 (José et al., 2014; Lamont et al., 2014; Roberts et al., 2014). In contrast, in the Southeast Madagascar Current,  
555 topographically-induced coastal upwelling brings cold, nutrient-rich water up to the surface, which supports high rates of  
556 primary production (Lutjeharms and Machu, 2000; Ho et al., 2004; Quartly and Srokosz, 2004). This upwelling and its  
557 impacts are observed in both the austral summer and winter (Ho et al., 2004).

558

559 The Agulhas Current itself is warm and oligotrophic with sources derived from low nutrient and low chlorophyll surface  
560 waters from the Mozambique Channel, Southeast Madagascar Current and the southwestern tropical Indian Ocean (Fig. 5;  
561 Lutjeharms, 2006). Chlorophyll *a* concentrations and production rates in Agulhas Current surface waters are particularly  
562 low during austral summer ( $< 0.2 \text{ mg/m}^3$  and  $< 500 \text{ mgC m}^{-2} \text{ d}^{-1}$ ) with higher concentrations and rates in the austral winter  
563 (Machu and Garcon, 2001; see Figs. 5, 6 and 20 in Hood et al., 2017). The Agulhas Current can drive upwelling and elevate  
564 primary production in the coastal zone through meandering and topographic interactions, but it can also dramatically  
565 suppress primary production when it impinges onto the shelf (Schumann et al., 2005).

566

567 In general, chlorophyll concentrations and primary production are elevated in the coastal zone of southeast Africa along the  
568 inshore side of the Agulhas Current (Fig. 5; Machu and Garcon, 2001; Goschen et al., 2012; see Figs. 5, 6 and 20 in Hood  
569 et al., 2017). This enhancement is most pronounced in austral summer and further southward downstream, and it is  
570 associated with upwelling favourable (easterly) winds and the aforementioned topographically-induced upwelling.

### 571 4.2.3 Interior flows

#### 572 4.2.3.1 Circulation

573 In the central-eastern South Indian Ocean between 20°S and 30°S, the surface geostrophic flow is generally eastward,  
574 opposite to the prediction both of the Ekman and Sverdrup theories (Sharma 1976; Sharma et al., 1978; Godfrey and  
575 Ridgway, 1985; Schott et al., 2009). This flow is driven by the large-scale, poleward drop in the dynamic height (steric  
576 height) near the surface (Godfrey and Ridgway, 1985; Schott et al., 2009) related to the meridional transition from the very  
577 fresh and warm SEC waters to the increasingly cooler, saltier and denser waters to the south. The flow generally extends  
578 from the sea surface to ~200–300 m (Domingues et al., 2007; Palastanga et al., 2007; Divakaran and Brassington, 2011;  
579 Menezes et al., 2014).

580

581 Embedded in this general eastward flow are narrower eastward jets (Maximenko et al., 2009; Divakaran and Brassington,  
582 2011; Menezes et al., 2014), collectively known as the South Indian (Ocean) Countercurrent (SICC; Palastanga et al. 2007;  
583 Siedler et al. 2006; Menezes et al., 2014). They start out as a single jet emanating from the southern tip of Madagascar  
584 around 25°S, possibly fed by a partial retroflexion of the SEMC (Palastanga et al., 2007; Siedler et al., 2006, 2009).  
585 Numerical particle tracking experiments conducted by Siedler et al. (2009) show that about 40% of the SICC transport  
586 originates from the SEMC region. The SICC flow divides into separate jets around the Central Indian Ridge (65°E–68°E),  
587 and continues to the west coast of Australia  
588 (Menezes et al., 2014). Eastward flows exist in similar latitude bands in the North and South Pacific and North and South  
589 Atlantic (Yoshida and Kidokoro, 1967; Merle et al., 1969; Takeuchi, 1984; Kubokawa, 1999; Qiu and Chen, 2004; Kobashi  
590 and Kubokawa, 2012). However, the jets in these basins are weaker and shallower than the SICCs and do not extend all the  
591 way to the eastern boundary (Menezes, 2015).

592  
593 Three main jets (Fig. 10a) are evident in geostrophic velocity calculated from both altimetric sea surface height and  
594 hydrography and are captured in OGCMs (Maximenko et al., 2009; Divakaran and Brassington, 2011; Menezes et al., 2014).  
595 The stronger southern jet (3–4 Sv) crosses the basin around 26°S and has an associated thermal front at depths around 100–  
596 200 m (Sharma 1976; Siedler et al., 2006; Menezes et al., 2014; Palastanga et al., 2007). This front suggests that the southern  
597 SICC has physics similar to the Subtropical Countercurrents (STCCs) of the Pacific Ocean (Kubokawa, 1999; Kobashi and  
598 Kubokawa, 2012, Menezes et al., 2014). The STCC mechanism, however, does not explain the central and northern  
599 branches (Menezes et al., 2014).

600  
601 The central branch of the SICC is found east of 75°–80°E, between 22° S and 24°S, and has a volume transport between 0.5  
602 Sv and 3–5 Sv (Menezes et al., 2014). The shallowest and weakest northern SICC jet (1 Sv) has an equatorward orientation  
603 and flows on the southern flank of the northern cell of the subtropical gyre (Palastanga et al., 2007; Menezes et al., 2014).  
604 Part of the northern SICC merges with the Eastern Gyral Current (EGC) around 15°S, 100°E (Fig. 10a). The eastward  
605 flowing EGC is part of an anticyclonic recirculation centred at the Indonesian-Australian basin (5°S–20°S and 100°E–  
606 125°E) (Domingues et al., 2007; Menezes et al., 2013, and references therein). Both the SICC and the EGC supply water  
607 to the Leeuwin Current (LC) and are an essential component of the LC dynamics (Domingues et al., 2007; Benthuisen et  
608 al., 2014; Lambert et al., 2016; Furue et al., 2013, 2017; Yit Sen Bull and van Sebille, 2016).

609  
610 The EGC and the SICC are dynamically distinct, however. In the EGC region, salinity overwhelms the temperature  
611 contribution to density gradients to generate near-surface eastward geostrophic vertical shear (Menezes et al., 2013). This  
612 salinity front is formed by the encounter of the fresh Indonesian Throughflow Water carried westward by the SEC-and the  
613 salty subtropical underwater (SUW) formed at the Southern Indian Ocean subtropical salinity maximum. The seasonal  
614 cycles of the EGC and the SICC are also distinct: the EGC is stronger in austral winter (3–5 Sv) and weaker (<0.5 Sv) in

615 summer with the cycle in phase with the Leeuwin Current (Feng et al., 2003; Menezes et al., 2013; Furue et al., 2017). The  
616 SICC, is overall stronger in spring-summer and weaker in winter (Palastanga et al., 2007; Jia et al., 2011a; Menezes et al.,  
617 2014). It experiences strong interannual variability, which peaks at biennial timescales and is decadal modulated (Menezes  
618 et al., 2016).

619

620 The multiple jets of the SICC are embedded in a zone of high eddy kinetic energy, with eddies generated by instabilities of  
621 the Leeuwin Current and of the SICC itself (Palastanga et al., 2007; Divakaran and Brassington, 2011; Huhn et al., 2012;  
622 Jia et al., 2011a, 2011b; Menezes et al., 2014, 2016; Siedler et al., 2006). By co-locating Argo floats and satellite data,  
623 Dilmahamod et al. (2018) described the passage of surface and subsurface South Indian Ocean eddies (SIDDIES). These  
624 westward-propagating, long-lived features (>3 months) originate in areas of high evaporation in the eastern Indian Ocean  
625 and prevail over a preferential latitudinal band, forming a permanent structure linking the eastern to the western Indian  
626 Ocean (the “SIDDIES Corridor”). This corridor of eddy passage allows the advection of water masses and biogeochemical  
627 properties across the basin (Dilmahamod et al., 2018).

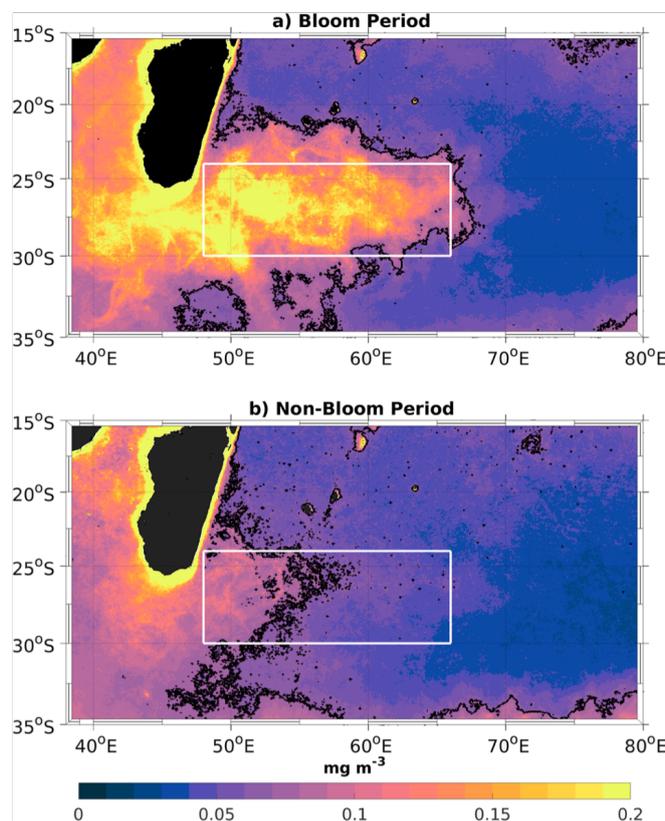

628

629 The location and strength of the SICC vary between studies, from well-defined jets (Siedler et al. 2006, Palastanga et al.  
630 2007, Divakaran and Brassington 2011, Menezes et al. 2014) to a mean velocity structure (Jia et al., 2011a), or even absence  
631 of the SICC (Srokosz et al. 2015). Depending on the region and time in which its characteristics were determined, the SICC  
632 varies from a weak mean current of 2–3 cm/s (Jia et al., 2011a) to a strong jet of 50 cm/s eastward flow (Siedler et al., 2006).

633

#### 634 4.2.3.2 Biogeochemical Variability

635 The near-surface eastward flows are generally associated with very low (oligotrophic) nutrient and chlorophyll-*a* (Chl-*a*)  
636 concentrations (< 0.1 mg/m<sup>3</sup>) and also very low primary production (< 500 mgC m<sup>-2</sup> d<sup>-1</sup>; Fig. 5 and see Figs. 5 and 6 in  
637 Hood et al., 2017). A well-defined deep Chl-*a* maximum is observed between 50 and 150 m during the austral fall along  
638 55°E between 20 and 30°S (Coles et al., unpublished data). An exception to this, however, is the South-East Madagascar  
639 bloom (SMB). The SMB occurs in near-surface waters off the southeastern coast of Madagascar in the late austral  
640 summer/fall (Jan-April). It was first described as a dendroid bloom by Longhurst (2001), owing to its branching shape that  
641 projects eastward (Fig. 11). The bloom can extend over a 2,500 km<sup>2</sup> area with Chl-*a* concentrations reaching 2-3 mg/m<sup>3</sup>  
642 (Longhurst, 2001), making it a ‘hot spot’ for primary production in an otherwise oligotrophic region. Fig. 11 illustrates the  
643 bloom’s large spatial variability, with high Chl-*a* filaments apparently co-occurring and being transported with mesoscale  
644 and submesoscale eddies and jets.

645

646 **Figure 11: (a) Spatial maps of mean Chl-*a* concentration (mg/m<sup>3</sup>) during months of maximum austral summer**  
647 **bloom. (b) Same as (a) but during January of minimum Chl-*a* concentration in austral summer. The black contour**  
648 **denotes the 0.07 mg/m<sup>3</sup> threshold used to distinguish between bloom and non-bloom years. From Dilmahamod et al.**  
649 **(2019).**

650 Why the SMB flourishes in late austral summer is unclear. Longhurst (2001) attributed SMB development to mixed layer  
651 deepening and entrainment of nutrients by the vigorous mesoscale eddy field. These nutrients could stimulate phytoplankton  
652 growth in the photic zone, with the eddies shaping the eastward propagation of the enhanced surface Chl-*a* concentrations.  
653 However, Uz (2007), Srokosz and Quartly (2013), and Dilmahamod et al. (2019) subsequently showed that the bloom occurs  
654 within a warm (> 26.5°C), shallow mixed layer (~30 m) overlying a strong pycnocline. Furthermore, they suggested that  
655 diazotrophs known to inhabit the region (Poulton et al., 2009) might introduce new nitrogen (N) from N<sub>2</sub> fixation that could  
656 support the enhanced Chl-*a* concentration as observed elsewhere (Mulholland et al., 2014; Hood et al. 2004; Coles et al.,  
657 2004). Subsequent studies also highlight the role of mesoscale eddies (Fig. 11), that could advect, disperse and co-mingle

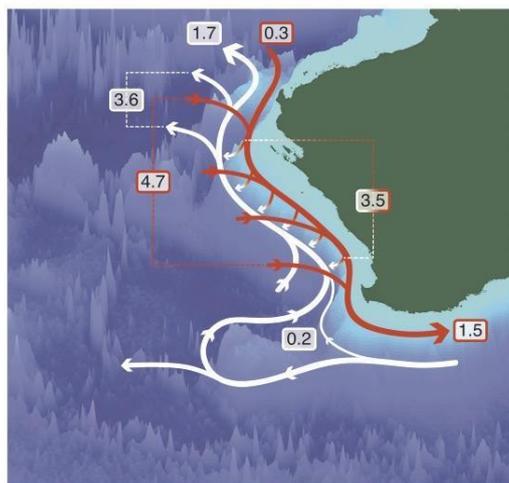

658 nutrients and/or phytoplankton biomass (Dilmahamod et al. 2019; Huhn et al., 2012; Raj et al., 2010; Srokosz and Quartly,  
659 2013; Srokosz et al., 2004, 2015; Uz, 2007).

660 A different explanation of the SMB and its eastward projection was proposed by Srokosz et al. (2004). In their proposed  
661 mechanism, the bloom initiates off Madagascar due to coastal processes that bring limiting nutrients to the photic zone and  
662 phytoplankton are transported horizontally by mesoscale eddies, resulting in an eastward propagation of the bloom.  
663 Dilmahamod et al. (2020) extend this further using a model to suggest that, from a nutrient flux analysis, horizontal advection  
664 of low-salinity nutrient-rich Madagascan coastal waters can indeed trigger a phytoplankton bloom. Alternatively, the  
665 apparent eastward propagation of the SMB has recently been attributed to advection by the SICC (Fig. 10; Dilmahamod et  
666 al., 2019; Huhn et al., 2012; Wilson and Qiu, 2008). Indeed, Huhn et al. (2012) further suggested that the bloom is shaped  
667 by a meridional barrier of jet-like Lagrangian coherent structures associated with the SICC.

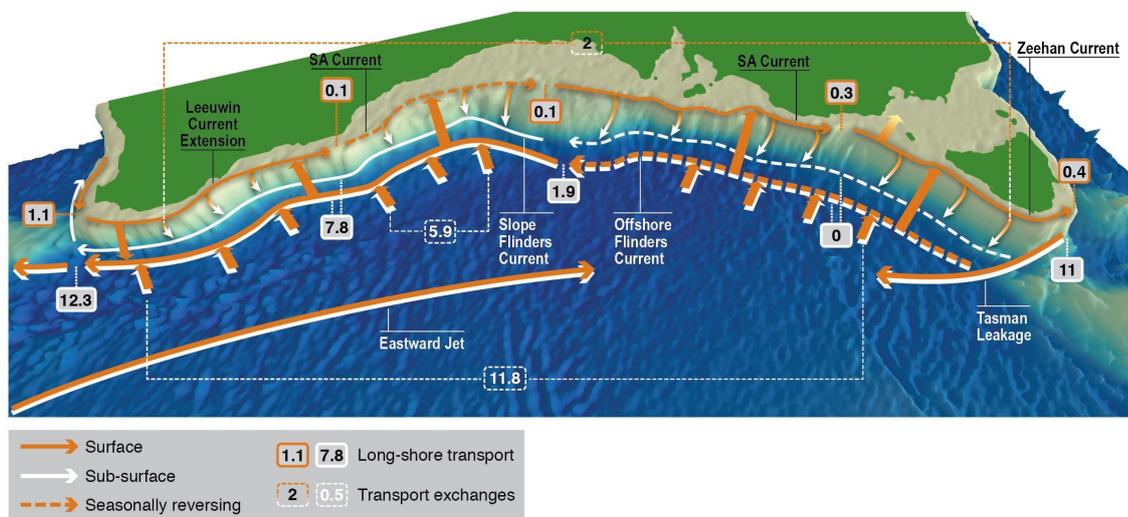

#### 668 4.2.4 Eastern Boundary

##### 669 4.2.4.1 Circulation

670 Unlike any other eastern boundary current, the Leeuwin Current (LC; Figs. 10 and 12a) flows poleward, along the shelf  
671 break of the west coast of Australia (Smith et al., 1991). Figure 12a presents the long-term average volume transport of the  
672 LC System from an observational climatology (Furue et al., 2017). The LC system includes the Leeuwin Undercurrent and  
673 exchanges with the interior zonal flows, where near-surface eastward flow enters the LC, flows poleward and at the same  
674 time sinks to the Leeuwin Undercurrent depths, flows equatorward, and finally moves westward out of the LC System. The  
675 primary source waters for the LC are the interior eastward flows (Section 4.2.3.1) that turn southeastward as they approach  
676 the coast and merge with the LC (Fig. 12a; Domingues et al., 2007; D'Adamo et al., 2009; Menezes et al., 2013, 2014; Furue  
677 et al., 2017, 2019). The LC carries 0.3 Sv southward at 22°S, gains 4.7 Sv from the Indian Ocean interior, loses 3.5 Sv  
678 through downwelling to the layer beneath, and carries 1.5 Sv at its southern limit. The LC is approximately 200–300 m  
679 deep, extends from 22°S (North West Cape) to 34°S (Cape Leeuwin) and exists throughout the year despite significant  
680 seasonality (Feng et al., 2003; Ridgway and Godfrey, 2015; Furue et al., 2017). The Holloway Current, which flows  
681 southwestward on the North West Shelf (D'Adamo et al., 2009; Bahmanpour et al., 2016), is another weaker source to the  
682 LC from the north. Inshore of the LC, there exist seasonal equatorward flows that recirculate waters of distinct watermass  
683 properties influenced by air-sea interaction over the continental shelf (Woo et al., 2006).

684

695

696 Beneath the LC, the Leeuwin Undercurrent exists in a depth range of 200-900 m, just offshore of the LC (Furue et al., 2017).  
697 It is fed in the south by a weak northward deflection of the Flinders Current, and a stronger northeastward recirculation of  
698 the Flinders Current around topography. The Leeuwin Undercurrent carries 0.2 Sv northward at its southern end, receives  
699 3.5 Sv downwelled from the layer above, loses 3.6 Sv to westward flow into the Indian Ocean interior, and carries 1.7 Sv  
700 northward at its northern end near 22°S (Furue et al., 2017)

701  
702 The LC flows around the southwestern corner of Australia and continues to flow eastward along the shelf break of the south  
703 coast of Australia to reach the southern tip of Tasmania near 42°S, 140°E (Fig. 12b, Oliver et al., 2016; Oke et al., 2018;  
704 Duran et al., 2020). This 5500-km long boundary current was first documented as a continuous flow by Ridgway and  
705 Condie (2004). When the longshore current is weak, however, it tends to be somewhat fragmentary (Oke et al., 2018; Duran  
706 et al., 2020) and sometimes even reverses in places (Duran et al., 2020). For this reason, and additionally because of the  
707 scarcity of observational sampling, the current is not traditionally regarded as a single current. Along southern Australia,  
708 the boundary currents can be described following Ridgway and Condie's (2004) naming convention. The current's western  
709 sector is called the Leeuwin Current Extension, the central part, to the south of the Great Australian Bight, is called the  
710 South Australian Current, and the easternmost part along Tasmania is called the Zeehan Current. They are collectively  
711 known as the Shelf-Break Currents (SBCs) of the Southern Australia Current System (Duran et al., 2020).

712  
713 As a poleward boundary current, the LC waters are relatively fresh and warm from tropical origins (Rochford, 1969;  
714 Andrews, 1977; Legeckis and Cresswell 1981; Domingues et al., 2007; Woo and Pattiaratchi, 2008). As the LC flows  
715 poleward, the saltier Indian Central Water, the surface water of the Subtropical South Indian Ocean, joins the LC  
716 (Section 4.2.3.1). At the same time, the mean density of the LC becomes higher as it flows poleward, partly because of the  
717 continual eastward inflow joining the LC and partly because of surface cooling (Woo and Pattiaratchi, 2008; Furue, 2019).  
718 The SBCs also carry warmer water eastward along the south coast of Australia (Ridgway and Condie, 2004).

719  
720 The LC's mean state is driven by the meridional pressure gradient in the upper ocean (e.g., Godfrey and Ridgway, 1985;  
721 Godfrey and Weaver, 1989, 1991), evident as a large poleward decrease in SSH balanced by an eastward surface geostrophic  
722 current (Section 4.2.3.1). The eastward flow approaches the eastern boundary, inducing downwelling and a surface poleward  
723 current (Fig. 12; Godfrey and Ridgway, 1985; McCreary et al., 1986; Thompson, 1987; Weaver and Middleton, 1989, 1990;  
724 Furue et al., 2013; Benthuisen et al., 2014), in opposition to the southerly winds. The mechanisms that determine the vertical  
725 extent of the interior eastward flow remains unclear. Offshore of the LC, this eastward flow exists over the upper 200 m in  
726 OGCMs and below that level the flow is weakly westward (Domingues et al., 2007; Furue et al., 2017). This depth coincides  
727 with the depth of the shelf break and the bottom of the LC; this correspondence may be achieved by the westward  
728 propagation of baroclinic Rossby waves (Weaver and Middleton, 1989; Furue et al., 2013).

729

730 It is not clear whether the SBCs along the south coast of Australia are, dynamically, an extension of the LC. The SBCs are  
731 at least consistent with the local northward Ekman drift (Ridgway and Condie, 2004; Duran et al., 2020) and hence would  
732 exist without the LC.

733  
734 On seasonal timescales, the LC transport generally tends to be strongest in austral autumn and weakest in austral summer  
735 (McCreary et al., 1986; Smith et al., 1991; Feng et al., 2003; Furue et al., 2017). There are two theories to explain this  
736 seasonality. In one, the local winds, which generally induce an offshore Ekman drift and therefore tend to weaken the LC,  
737 reach their annual maximum or minimum when the LC transport reaches its minimum or maximum, respectively (McCreary  
738 et al., 1986; Furue et al., 2013). In the other, a seasonal pressure anomaly originates in the Gulf of Carpentaria and propagates  
739 counterclockwise along the shelf break, driving the seasonality of the LC and of the SBCs to the south of Australia (Ridgway  
740 and Godfrey, 2015). Like the LC, the SBCs tend to be strongest in austral autumn and weakest in austral summer (Ridgway  
741 and Condie, 2004; Oke et al., 2018; Duran et al., 2020). In particular, the eastern part of the South Australian Current is seen  
742 to reverse in summer in Duran et al.'s (2020) analysis. This variability is consistent with the counterclockwise propagation  
743 of pressure anomaly shown by Ridgway and Godfrey (2015) and also with the seasonality of the wind stress along the south  
744 coast of Australia, with onshore (offshore) Ekman drift tending to drive eastward (westward) shelf-break flow (Duran et al.  
745 2020). Again it is not clear which mechanism dominates the seasonality of the SBCs.

746  
747 On interannual time scales, the LC is modulated by the El Niño Southern Oscillation owing to the steric height anomalies  
748 in the western equatorial Pacific Ocean propagating through the Indonesian Seas and along Western Australia (Feng et al.,  
749 2003). During El Niño and La Niña periods, the LC transport weakens and strengthens, respectively, and is correlated with  
750 Fremantle sea level (Feng et al., 2003). During the strong 2010–2011 La Niña event, the LC reached record strength speeds  
751 (Feng et al., 2013) and the consequences of this event are described in Section 7.4. On multidecadal timescales, the major  
752 boundary currents around Australia, including the LC, are reported to have strengthened during 1979–2014 in an eddy-  
753 resolving OGCM, consistent also with observations (Feng et al., 2016; see Section 6.1.2 for associated changes). At  
754 intraseasonal timescales, winds or heat anomalies on the North West Shelf region due to MJO events lead to intraseasonal  
755 variability of the Holloway Current on the North West Shelf and then of the LC (Marshall and Hendon, 2014; Marin and  
756 Feng, 2019).

757  
758 The LC is accompanied by mesoscale eddies that cause the LC to meander energetically (Pearce and Griffiths, 1991; Feng  
759 et al., 2005; Waite et al., 2007; Meuleners et al., 2008). Those eddies are, at least partially, generated by barotropic,  
760 baroclinic, or mixed instability of the LC itself (Pearce and Griffiths, 1991; Feng et al., 2005; Meuleners et al., 2008). The  
761 eddy kinetic energy is greatest when the LC transport is strongest, in May–June ( Fang and Morrow, 2003; Feng et al.,  
762 2005). Some of these eddies cause a large meander of the LC: a large anti-cyclonic eddy often forms at 28°–29°S and at  
763 31°–32°S (Feng et al., 2003; Feng et al., 2007) and in this case, the LC leaves the continental shelf and flows offshore around

764 this eddy before coming back to the continental shelf. This state typically starts during May–June and ends in July–August  
765 (Feng et al., 2007). Similarly, it is suggested that the eastern part of the SBCs becomes unstable in boreal autumn and winter,  
766 generating eddies, which subsequently propagate westward south of Australia (Oke et al., 2018).

767  
768 Just below the Leeuwin Current is the equatorward Leeuwin Undercurrent (LUC; Thompson, 1984; Church et al., 1989;  
769 Smith et al., 1991; Fig. 12a). The LUC hugs the continental slope and extends from 200 m to 800 m (Furue et al., 2017).  
770 The LUC begins at Cape Leeuwin (34°S, 114°E) and is fed by a northward bend of a small fraction of the Flinders Current  
771 (FC; Furue et al., 2017; see Fig. 10 for the pathway of FC). The remaining part of the FC keeps flowing westward but  
772 another small fraction of it appears to retroflect eastward and join and augment the LUC (Duran, 2015; Furue et al., 2017).  
773 Near 22°S, most of the LUC volume leaves the continental slope and flows offshore (Duran, 2015), apparently following  
774 the southern flank of the Exmouth Plateau although its bottom at 900 m is much shallower than the topographic feature.

775  
776 To the south of Australia, an undercurrent has been recently identified below the Zeehan Current in a numerical simulation  
777 (Oke et al., 2018) and in a geostrophic calculation based on a gridded T–S climatology (Duran et al., 2020). Traditionally  
778 this flow was identified as a branch of the FC (Cirano and Middleton, 2004; Rosell-Fieschi et al., 2013; Feng et al., 2016)  
779 because the former flows in the same direction as the latter, but the FC as the northern boundary current of the Subtropical  
780 Gyre cannot exist on an eastern boundary (Anderson and Gill, 1975; Philander and Yoon, 1982; McCreary et al., 1992) and  
781 it does not have a vertical structure of an undercurrent (Duran et al., 2020). This northwestward- or westward-flowing  
782 undercurrent appears to exist all the way from the west coast of Tasmania to Cape Leeuwin (the southwestern tip of  
783 Australia) but its separation from the FC is less clear to the south of the Great Australian Bight and further west, where the  
784 FC starts to accelerate and tends to overwhelm the undercurrent (Duran et al., 2020). Below, we call this current “slope FC”  
785 following Duran et al. (2020).

786  
787 The mechanisms responsible for the undercurrents off Western Australia remain an open question, although models have  
788 been developed to investigate potential processes. The linear, continuously stratified models of McCreary et al. (1986) and  
789 Kundu and McCreary (1986) produce a surface poleward and a subsurface equatorward current, resembling the LC and  
790 LUC, along the eastern boundary. This class of model, however, requires large vertical diffusivity to produce realistic LC  
791 and LUC (McCreary, 2013, personal communication). Along a continental slope, alongshore and cross-shelf buoyancy  
792 advection cause a shelf break front, forming a surface intensified poleward current, like the LC, and an equatorward  
793 undercurrent by thermal wind shear (Benthuisen et al., 2014). Analytical shelf models have been extended to include cross-  
794 shelf buoyancy gradients to derive a poleward undercurrent like the LUC (Schloesser, 2014). These process-based analytical  
795 theories have not been tested in an eddy-resolving model.

796

797 The LUC and the slope FC are connected to the LC and the SBCs, respectively, by downwelling (Fig. 12; Furue et al., 2017;  
798 Duran et al., 2020), suggesting a common, but as yet unexplained, dynamics. Note, however, that for the LC–LUC pair, the  
799 mean downwelling appears to occur along isopycnal surfaces, and hence the LC water mass is not found in the LUC (Furue,  
800 2019). For the SBCs and the slope FC, the nature of the downwelling is not known. The seasonality of these undercurrents  
801 are not well known. No systematic seasonal variability of the LUC was evident in a hydrographic climatology and ocean  
802 general circulation model (Furue et al., 2017).

803

#### 804 4.2.4.2 Biogeochemical Variability

805 The tropical source waters and downwelling tendency of the Leeuwin Current combine to create a warm, oligotrophic  
806 current with low productivity. Chl-*a* concentrations are usually  $< 30 \text{ mgChl}a \text{ m}^{-2}$  and rates of primary production rates  
807 generally do not exceed  $500 \text{ mgC m}^{-2} \text{ d}^{-1}$  (Koslow et al., 2008; Lourey et al., 2006; Lourey et al., 2013). Productivity in the  
808 Leeuwin Current is lowest during austral summer, when the water column is stratified. During summer, subsurface  
809 chlorophyll maxima are found between 50 and 120 m depth (Hanson et al., 2007) as observed in open ocean subtropical  
810 oligotrophic waters (e.g., Venrick, 1991). However, rates of primary production in near shore upwelling regions (e.g., off  
811 of the North West Cape during summer) can sometimes attain very high levels ( $3000\text{--}8000 \text{ mgC m}^{-2} \text{ day}^{-1}$ ) as observed  
812 in other eastern boundary upwelling zones (Furnas, 2007).

813 In all seasons, meanders in the Leeuwin Current give rise to warm core, anticyclonic eddies that carry moderately high  
814 chlorophyll coastal water offshore. The elevated chlorophyll concentrations in these eddies is due to the presence of coastal  
815 diatom communities. These diatoms are transported offshore into cooler oligotrophic waters that are dominated by much  
816 smaller open ocean phytoplankton species (Waite et al., 2007a; Paterson et al., 2008; Waite et al., 2016). These eddies,  
817 which can extend to more than 2000 m depth, are unusual because they are downwelling (anticyclonic) circulations that  
818 should inhibit the input of new nutrients from depth. Nonetheless, these eddies, and the elevated chlorophyll concentrations  
819 that are associated with them, persist for months (Feng et al., 2007; Moore et al., 2007; du Fois et al., 2014). It has been  
820 hypothesized that the diatom communities in these eddies are supported by internal nutrient recycling and/or lateral supply  
821 (Waite et al., 2007a; Paterson et al., 2013; Thompson et al., 2007).

822 Generation of these warm (and cold) core eddies by the Leeuwin Current is prolific between  $20^\circ$  and  $35^\circ$  S (Gaube et al.,  
823 2013). Most of these eddies move directly westward and some may be very long-lived (Feng et al., 2005; Feng et al., 2007;  
824 Moore et al., 2007; Gaube et al., 2013; du Fois et al., 2014). The persistence and potential biogeochemical/ecological  
825 impacts of these eddies in the open ocean have not been investigated fully.

## 826 4.3 Equatorial regime

### 827 4.3.1 Wyrтки Jets

828 Owing to the seasonally reversing monsoon winds, the equatorial Indian Ocean (EIO) exhibits unique characteristics and is  
829 in contrast with the equatorial Atlantic and Pacific Oceans. Unlike the other basins, the annual winds along the EIO are very  
830 weak and mostly meridionally oriented except during the two intermonsoon seasons between boreal winter (April-May) and  
831 summer (Oct-Nov) when strong westerly wind bursts prevail along the EIO (see Schott and McCreary, 2001 and references  
832 therein). These westerly winds force strong eastward jets in the top 100 m along the equator and are known as spring and  
833 fall Wyrтки Jets, respectively (Wyrтки, 1973). These surface jets are usually confined within the top 100 m of the water  
834 column (Han et al., 1999; Iskander et al., 2011) and deepen (shoal) the thermocline and elevate (lower) the sea level in the  
835 east (west) (Rao et al., 1989; Schott and McCreary, 2001; Nagura and McPhaden, 2010a). These jets play a major role in  
836 zonal redistribution of mass, heat, salt and other water properties at the Equator and in off-equatorial basins (Reppin et al.,  
837 1999; Murtugudde and Busalacchi, 1999; Han et al., 1999; McPhaden et al., 2015; Chatterjee et al., 2017). Long term ADCP  
838 observations from the RAMA equatorial mooring suggests that the fall jet in the central EIO is usually stronger with a  
839 maximum transport of  $\sim 19.7$  Sv compared to the spring jet which shows maximum transport of  $\sim 14.9$  Sv with comparable  
840 standard deviations (McPhaden et al., 2015).

841 These eastward surface zonal currents tend to propagate westward during spring and eastward during fall (Nagura and  
842 McPhaden, 2016). The westward phase propagation speed during spring is estimated to be on average between 0.7-1.5 m  
843  $s^{-1}$  (Qiu et al., 2009; Nagura and McPhaden, 2010a) and driven primarily by the westward propagating surface zonal winds  
844 associated with atmospheric deep convection that moves from the Maritime Continent to the northern Bay of Bengal during  
845 Spring (Nagura and McPhaden, 2010b; Nagura and McPhaden, 2016). Equatorial Rossby waves may be also contributing  
846 to this westward propagation (Nagura and McPhaden, 2010a). In contrast, during fall, as the deep convection moves  
847 southeastward, the surface equatorial zonal winds, and thus surface currents, propagate eastward.

848 The spring and fall Wyrтки Jets also show considerable intraseasonal and interannual variability. While the intraseasonal  
849 variability of the Wyrтки Jets has been shown to be influenced by their own instability (Sengupta et al., 2001, 2007; Han et  
850 al., 2004) and local winds (Masumoto et al., 2005, Sengupta et al., 2007, Iskander et al., 2009; Prerna et al., 2019), the  
851 interannual variability of the Wyrтки Jets is mainly caused by the anomalous wind forcing along the EIO associated with  
852 ENSO (Murtugudde et al., 2000; Gnanaseelan et al., 2012; Joseph et al., 2012) and IOD (Nagura and McPhaden, 2010b;  
853 Prerna et al., 2019): IOD weakens (strengthens) the equatorial zonal winds during its positive (negative) phase. While IOD  
854 modulates the zonal winds along the entire equator, the influence of ENSO is primarily limited to the eastern part of the EIO  
855 (Gnanaseelan et al., 2012). Moreover, it has been shown that these climate modes affect the boreal fall jet more significantly  
856 than the boreal spring jet. Recent modelling studies suggest that MJO convection can lead to a stronger spring Wyrтки jet

857 particularly in the eastern EIO. The interannual variability of MJO, therefore, can contribute to the observed interannual  
858 variability of this equatorial jet as well (Deshpande et al., 2017; Prerna et al., 2019).

#### 859 **4.3.2 Meridional Circulation**

860 Meridional velocity along the equator shows prominent high frequency variability at all depths, but of higher frequencies in  
861 the periodic band of 10-20 days with a peak at ~15 days (also referred to as biweekly variability) and in the 20-30 days band  
862 with a peak at ~25 days.

863 The existence of the high frequency variability in the meridional velocity is observed all along the EIO and across the entire  
864 depth range (Masumoto et al., 2005; David et al., 2011; Chatterjee et al., 2013; Smyth et al., 2014) and is attributed to Yanai  
865 waves (also referred to as mixed Rossby-Gravity waves). Unlike Kelvin and Rossby waves, Yanai wave phases can  
866 propagate westward or eastward depending upon their frequency, but their group velocity is always eastward. The spatial  
867 structure of these waves resembles that of the Tropical Instability Waves (TIWs) of the equatorial Pacific and Atlantic and  
868 hence, exhibits convergent meridional heat flux into the equatorial regime (Shinoda, 2010; Smyth et al., 2014). While these  
869 waves were first observed in the late 1990s, the establishment of the equatorial RAMA moorings (McPhaden et al., 2009)  
870 over the last two decades has provided more insight into these processes. Bi-weekly (10-20 day) is shown to be forced by  
871 the direct meridional wind stress (Sengupta et al., 2004) and to some extent by the meridional gradient of the zonal wind  
872 stress (Miyama et al., 2006). The 20–30-day band can be excited by off-equatorial barotropic/baroclinic instabilities in  
873 addition to direct wind forcing. A detailed review of the biweekly variability is provided in Schott et al. (2009) and hence,  
874 in this review, we mainly focus on the 20-30 day variability.

875 While the 20-30-day oscillation in meridional velocity is reported near the surface in the central EIO (David et al., 2011),  
876 in the eastern EIO these variabilities are seen only in subsurface layers (100-200 m depth) of the water column (Masumoto  
877 et al., 2005). This indicates a possible downward energy propagation of a vertical beam that carries energy to deeper depths.  
878 In the central EIO these 20-30-day Yanai waves are excited by horizontal shear between the westward-flowing South  
879 Equatorial Current and the eastward-flowing Southwest Monsoon Current during IOD events (Fig. 10a; David et al., 2011).  
880 In the western EIO, these waves are primarily driven by cross equatorial meridional winds (Chatterjee et al., 2013). During  
881 early boreal summer (June/July), when the Somali current begins to cross the Equator along the western boundary of the  
882 basin, it bends offshore to conserve potential vorticity (Schott and McCreary, 2001) and forms a gyral circulation known as  
883 the Southern Gyre (Fig. 10a). Subsequently, these swift currents turn barotropically unstable and generate eddy flow that is  
884 advected southward to the Equator near the western boundary i.e. at ~50-55°E. They generate a westward propagating cross  
885 equatorial flow with a wavelength set by the eddy field which is similar to the wavelength of 20-30 days. Yanai waves and  
886 thus excite these frequencies efficiently (Chatterjee et al., 2013).

#### 887 **4.3.4 Equatorial Undercurrents**

888 Unlike in the Pacific and Atlantic Oceans, the Indian Ocean Equatorial Undercurrent (EUC) is a much weaker and seasonally  
889 varying transient feature driven by seasonally reversing monsoon winds (Reppin et al., 1999; Schott and McCreary, 2001).  
890 The equatorial RAMA moorings have recorded an eastward EUC with a core within the thermocline during boreal winter  
891 and spring (Chen et al., 2015, 2019) and occasionally in summer and fall at a depth of 90-170 m water column (Iskandar  
892 and McPhaden, 2011). During winter, the eastward EUC is forced by the upwelling Kelvin and Rossby waves that are in  
893 turn forced by the easterly winds along the equator; during summer the westward EUC is primarily forced by the eastward  
894 pressure gradient generated by the downwelling reflected Rossby waves off the eastern boundary of the basin. On  
895 intraseasonal timescales of 30-70-days, the EUC variability is dominated by that of Kelvin and Rossby waves of lower order  
896 baroclinic modes (Iskander and McPhaden, 2011).

#### 897 **4.3.4 Equatorial Upwelling**

898 In the absence of persistent equatorial easterlies, the EIO does not show a permanent upwelling in the eastern part as is seen  
899 in the Pacific and Atlantic Oceans. In the Pacific and Atlantic Oceans, permanent easterlies drive permanent equatorial  
900 upwelling, but in the Indian Ocean, the mean easterlies are weak or absent and permanent upwelling does not exist. Instead,  
901 coastal upwelling along the coasts of Sumatra and Java is prominent. During June-October, south-easterly trade winds blow  
902 close to the Equator and drive the offshore Ekman transport away from the Sumatra-Java coast (Quadfasel and Cresswell,  
903 1992; Sprintall et al., 1999; Susanto et al., 2001). The associated wind-driven upwelling intensifies as the monsoon  
904 progresses, reaching its peak by August and finally weakening by October as the monsoon winds wane. Recent studies  
905 suggest that when the easterly winds prevail during summer, upwelling favourable Kelvin waves also contribute to  
906 intensifying the equatorial upwelling (Iskander et al., 2009; Chen et al., 2016). During boreal winter-early spring (December-  
907 March), an intermittent/weaker subsurface thermocline shoaling is evident (Chen et al., 2016). Subsequently, the prevalence  
908 of westerly winds which drive downwelling Kelvin waves depress the thermocline in the east (Susanto et al., 2001; Prerna  
909 et al., 2019). Apart from this seasonal cycle, interannual climatic variability associated with ENSO and IOD events (Saji et  
910 al., 1999; Vinayachandran et al., 1999) also influences the upwelling intensity in this region (Section 7.2).

#### 911 **4.3.5 Biogeochemical Variability**

912 Much of the current understanding of biogeochemical variability in the equatorial zone of the Indian Ocean is based on  
913 satellite ocean color observations and models, augmented by some additional, relatively sparse, in situ measurements.  
914 Seasonal climatologies of near-surface chlorophyll concentrations and primary production show a significant seasonality in  
915 equatorial waters that is clearly associated with monsoon forcing (Fig. 5[1], Wiggert et al., 2006; Strutton et al., 2015; and  
916 see Figs. 5 and 6 in Hood et al., 2017). In general, Chl-*a* concentrations and primary production increase northward from  
917 the equator with the lowest concentrations ( $< 0.1 \text{ mg m}^{-3}$ ) and rates ( $< 800 \text{ mg C m}^{-2} \text{ d}^{-1}$ ) occurring during boreal spring

918 intermonsoon period. During the southwest monsoon, Chl-*a* concentrations and rates of primary production increase in  
919 western equatorial waters in response to monsoon-forced mixing and upwelling. However, concentrations and rates in the  
920 central and eastern equatorial waters stay relatively low ( $< 0.5 \text{ mg m}^{-3}$ ,  $< 800 \text{ mgC m}^{-2} \text{ d}^{-1}$ , respectively). Island wake effects  
921 can be seen advecting high chlorophyll water ( $> 0.5 \text{ mg m}^{-3}$ ) along the equator from the Chagos-Laccadive ridge at 73°E  
922 eastward during the autumn intermonsoon period and westward during spring (see Fig. 1 in Strutton *et al.*, 2015).

923 Well-developed deep Chl-*a* maxima have been observed in the equatorial Indian Ocean along 65°E centered at about 50  
924 meters in November-December (George *et al.*, 2013) and along 80°E centered at about 75 meters in August-September  
925 (Sorokin *et al.*, 1985). It is unknown whether or not this subsurface Chl-*a* maximum exists along the equator throughout  
926 the year, but it is probably present whenever the water column is stratified. Models predict the presence of a deep (60 m)  
927 Chl-*a* maximum in eastern Indian Ocean equatorial waters along 87°E (Wiggert *et al.*, 2006). This feature is present  
928 throughout the year (in the model) except when high chlorophyll surface water is advected into the region during the  
929 southwest monsoon.

930 As discussed above, the equatorial Indian Ocean is strongly influenced by physical processes at intraseasonal to interannual  
931 time scales (i.e., Wyrтки Jets, MJO and IOD).

932 All of these physical processes influence biogeochemistry. For example, IOD events can significantly increase chlorophyll  
933 concentrations and primary production in eastern Indian Ocean equatorial waters (Wiggert *et al.*, 2009). In addition,  
934 relaxation of an IOD can deplete upper ocean nutrients, decreasing biological productivity (Kumar *et al.*, 2012).  
935 Biogeochemical responses to the IOD also have significant higher trophic level impacts (Marsac and Le Blanc, 1999).

936  
937 Resplandy *et al.* (2009) used a combination of satellite observations and biophysical model simulations to show how  
938 chlorophyll concentrations and primary production just south of the equator, in the vicinity of the Seychelles-Chagos  
939 thermocline ridge, can be increased by MJO-induced wind mixing and nutrient entrainment. They also concluded that IOD-  
940 driven interannual variability of thermocline depth influences the biogeochemical response to MJO, i.e., following IOD  
941 events, the deepened nutricline inhibits nutrient input into the mixed layer, and thus decreases the biogeochemical response  
942 to MJO.

943 Based on model simulations Wiggert *et al.* (2006) argued that Wyrтки jets depress the thermocline and nitracline along the  
944 equator on the eastern side of the basin and, as a result, lower equatorial primary production when they arrive in the spring  
945 and autumn. This pattern was observed in a 25 day time series study on the equator at 80.5°E in late 2006 that showed a  
946 deepening of the surface layer, nitracline and subsurface Chl-*a* maximum during the autumn Wyrтки jet period (Kumar *et*  
947 *al.*, 2012).

948

949 Finally, Strutton et al. (2015) examined time-series measurements of near-surface chlorophyll concentration from a mooring  
950 that was deployed at 80.5 E on the equator in the Indian Ocean in 2010. These data revealed at least six spikes in chlorophyll  
951 from October through December, separated by approximately 2-week intervals. These events coincided with the  
952 development of the fall Wyrтки jets. Measurements from the mooring revealed that the chlorophyll pulses were associated  
953 with the increases in eastward surface winds and eastward currents in the mixed layer. Strutton et al. (2015) argued that  
954 these observations are inconsistent with upwelling dynamics because eastward winds that cause intensification of the Wyrтки  
955 jet should drive downwelling. They concluded that the chlorophyll spikes could be explained by two alternative mechanisms:  
956 (1) turbulent entrainment of nutrients and/or chlorophyll from across the base of the mixed layer by wind stirring or Wyrтки  
957 jet-induced shear instability or (2) enhanced southward advection of high chlorophyll concentrations into the equatorial zone  
958 associated with wind-forced biweekly mixed Rossby-gravity waves.

#### 959 4.4 Northern Indian Ocean

960 The two main basins of the northern Indian Ocean, the Bay of Bengal (BoB) and the Arabian Sea (AS), are characterized at  
961 the surface by remarkably contrasting sea surface salinity with differences of the order of 3 psu (e.g. Chatterjee et al. 2012,  
962 Gordon et al. 2016, Hormann et al. 2019) decreasing from west to east (Fig. 4). The fresh surface layer of the BoB is  
963 maintained by large freshwater input deriving from direct rainfall over the ocean and river runoff, especially during the  
964 South Asian monsoon. The salt balance of the BoB is maintained by the subsurface supply of salt water via the Southwest  
965 Monsoon Current (Fig. 10, Vinayachandran et al., 2013). The saltier SSS of the AS is the consequence of an evaporative  
966 regime (e.g., Rao & Sivakumar, 2003; Sengupta et al., 2006). A reversing monsoonal near-surface circulation (Fig. 10 a,b)  
967 plays a central role in the exchanges of freshwater and heat between the BoB and the AS (McCreary et al. 1993, Hormann  
968 et al. 2019).

969 Recent multi-year deployments of satellite tracked surface drifters drogued at 15 m depth (Wijesekera et. al, 2016,  
970 Centurioni et al. 2018) have helped to better constrain the amplitude and structure of the circulation and the exchange  
971 processes between the two basins, and to refine the findings reported by other authors (e.g. Schott and McCreary, 2001).  
972 Additionally, implementation of a moored buoy network along the slope and shelf of the Indian coast has helped significantly  
973 in enhancing our understanding of the east India Coastal Current (EICC) and west India Coastal Current (WICC) in the east  
974 and west coast of India, respectively (Mukherjee et al., 2014; Amol et al., 2014; Mukhopadhyay et al., 2020; Anya et al.  
975 2020).

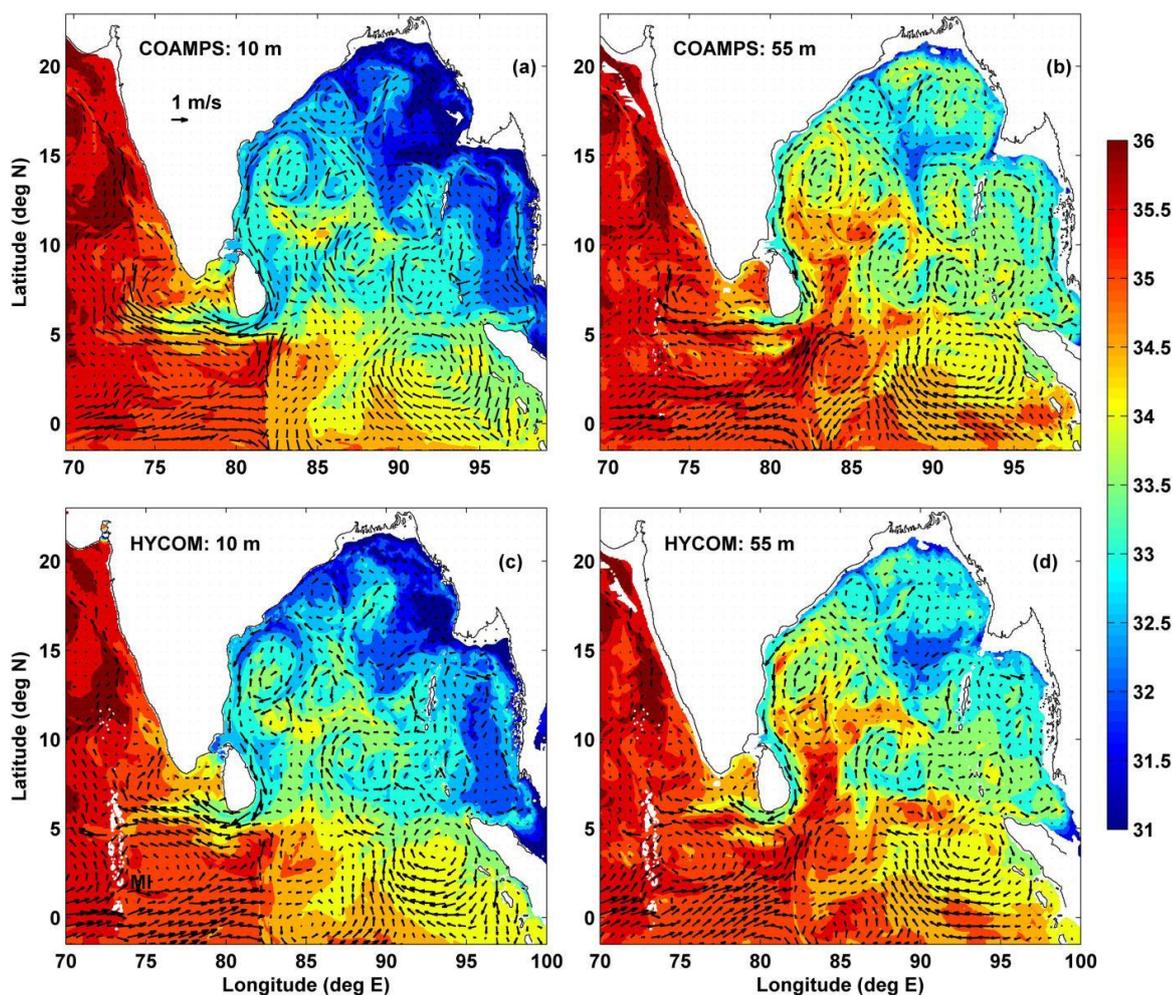

#### 976 4.4.1 Bay of Bengal

977 In a climatological sense, the main features of the near-surface circulation of the western BoB (Figs. 10a and 10b) are the  
978 reversing EICC, the Southwest/Northeast Monsoon Current (SMC/NMC) and the seasonally variable Sri Lanka Dome. The  
979 eastern side of the BoB, extending into the Andaman Sea, is characterised by a sluggish circulation.

980 **4.4.1.1 Southwest/Northeast Monsoon Currents**

981 During the boreal summer SW monsoon, the Southwest Monsoon Current (SMC, Fig. 10a) flows eastward around the Indian  
982 subcontinent supplying salty water from the Arabian Sea to the fresher Bay of Bengal (e.g., Jensen, 2001; Jensen et al.,  
983 2016; Vinayachandran et al., 2013; Wijesekera et al., 2015, 2016). During the winter monsoon, the Northeast Monsoon  
984 Current (NMC, Fig. 10b) reverses the flow carrying fresher water into the Arabian Sea. Figure 13 provides a snapshot from  
985 two operational forecast systems, the Coupled Ocean-Atmosphere Mesoscale Prediction System (COAMPS) and the 1/12°  
986 HYbrid Coordinate Ocean Model (HYCOM), of the NMC flow and route for freshwater to enter the Arabian Sea (Wijesekera  
987 et al., 2015).

988

989 **Figure 13: (top) COAMPS velocity vectors (arrows) and salinity (psu) (color shading) at (a) 10 m and (b) 55 m on 18**  
990 **December 2013. (bottom) HYCOM velocity vectors (arrows) and salinity distribution (psu) (color shading) at (c) 10**  
991 **m, and (d) 55 m. MI denotes Maldives Island chain. Taken from Wijeskeru et al. (2015).**

992 A more recent study has found that the origins of the Arabian Sea high salinity water are specifically from the western  
993 Arabian Sea and western Equatorial Indian Ocean, and they reach the Bay of Bengal via a combination of the Indian Ocean  
994 EUC and the SMC (Sanchez-Franks et al., 2019; Section 8.2). Changes in the supply of salty water to the Bay of Bengal  
995 varies interannually due to the strength in the equatorial currents, forced by the local wind field and ENSO (Sanchez-Franks  
996 et al., 2019), and is expected to influence the salinity budget of the Bay of Bengal (Vinayachandran et al., 2013) and thus  
997 modulate SST variability (Jensen et al., 2016; Li et al., 2017; Vinayachandran et al., 2013; Webber et al., 2018).

#### 998 4.4.1.2 East Indian Coastal Currents (EICC)

999 The EICC forms the western boundary current of the Bay of Bengal and plays an important role in the basin-scale heat and  
1000 salt budget of the Indian Ocean, and hence in determining the local climate (Shenoi et al, 2002), biological processes  
1001 (Madhupratap et al, 2003; Vinayachandran et al, 2005; Naqvi et al, 2006; Dileepkumar, 2006; McCreary et al, 2009) and  
1002 marine fisheries (Vivekananda and Krishnakumar, 2010) of this region. It reverses its direction seasonally north of 10°N in  
1003 response to a combination of local alongshore winds, remote alongshore winds in the eastern BoB, remote forcing from the  
1004 equatorial Indian Ocean and the interior Ekman pumping of the basin (Shankar et al., 1996; McCreary et al., 1996;  
1005 Vinayachandran et al., 1996; Mukherjee et al., 2017). The EICC is generally equatorward south of 10°N throughout the  
1006 year. While local winds dominate summer and winter, the remote forcing dominates during the inter-monsoon periods  
1007 (Shankar et al., 1996; McCreary et al., 1996; Suresh et al., 2013).

1008 Climatological ship-drift and hydrographic data suggest the EICC flows poleward during February-September (Shetye et  
1009 al., 1993) and turns equatorward during November-January (Shetye et al., 1996) (Fig. 10). During boreal spring (March-  
1010 May), the EICC is strongest with a magnitude exceeding 100 cm/s and shows unidirectional reasonably stronger currents  
1011 even in the deeper depths to about 150 m. This is the time when it forms the western boundary current of a cyclonic basin-  
1012 wide gyre of the BoB. At this time, the local alongshore winds are weakest and the stronger EICC is primarily forced by the  
1013 interior anticyclonic Ekman pumping over the basin (McCreary et al., 1996; Shankar et al., 1996; Vinayachandran et al.,  
1014 1996; Mukherjee et al., 2017). During summer, the EICC is weaker and is restricted to within the top 70 m of the water  
1015 column. The poleward flow is generally limited to the central part of the coast between 10-18°N and often switches to short  
1016 pulses of poleward currents along the coast (Mukherjee et al., 2018; Francis et al., 2020). The poleward flow is driven by  
1017 local winds, but the response of the interior cyclonic Ekman pumping and equatorial winds driving an opposite flow along  
1018 the coast causes a weaker poleward EICC than in spring (McCreary et al., 1996; Vinayachandran et al., 1996; Shankar et

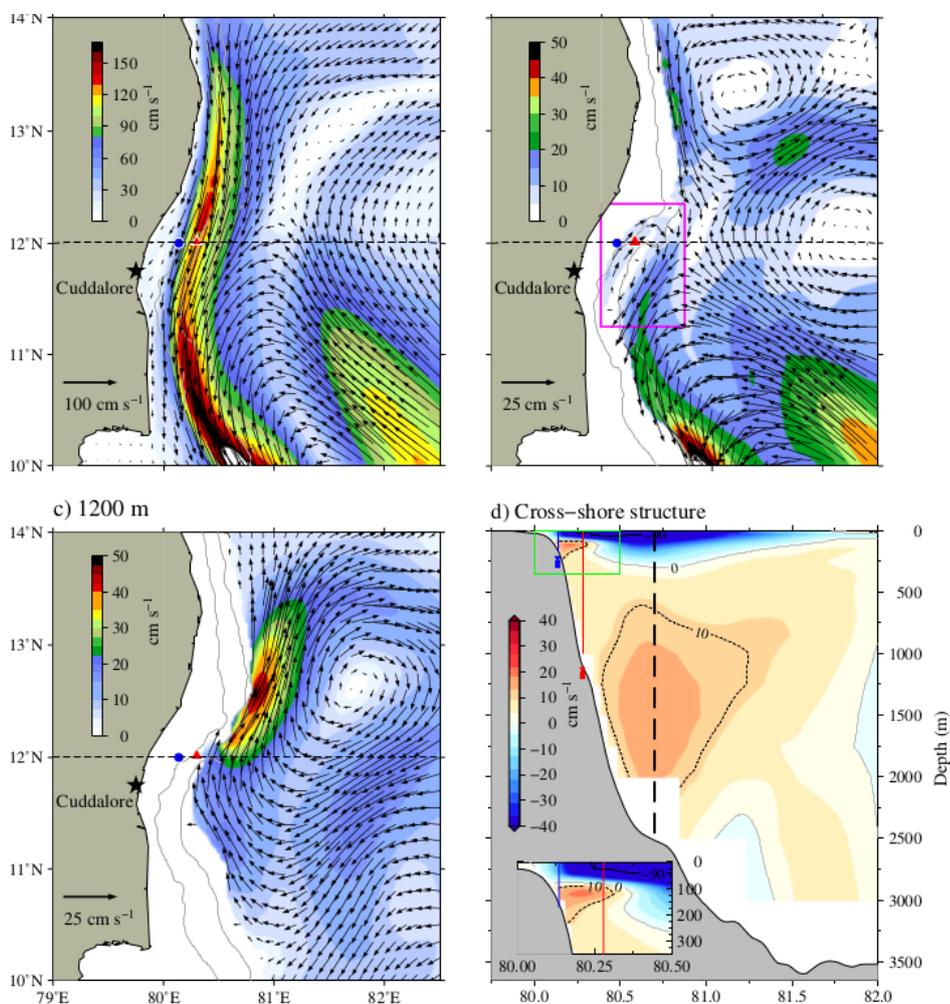

1019 al., 2002). The basin-scale gyre also disappears in summer and the EICC then consists of several eddies along the coast. The  
1020 EICC turns equatorward during November-January (Shetye et al., 1996).

1021 Along the east coast of India, ADCP observations reveal that variability in alongshore currents is dominated by seasonal  
1022 timescales Mukhopadhyay et al. (2010a). While the annual cycle is driven by local alongshore winds and interior Ekman  
1023 pumping, the semiannual cycle is the result of asymmetry in the monsoon and equatorial forcing (Mukherjee et al., 2018).  
1024 The seasonal reversal of the EICC is apparent all along the east coast, suggesting that the canonical directions of the EICC  
1025 are a robust feature and explaining their existence in ship-drift climatologies (Cutler and Swallow, 1984; Mariano et al.,  
1026 1995). In the annual band, upward phase propagation is evident all along the coast, suggesting the dominance of remote  
1027 forcing over local alongshore winds in driving the EICC.

1028 Near-surface alongshore currents also display significant 120 day and intraseasonal variability. The magnitude of the 120  
1029 day variability is generally weaker than the semiannual period, particularly in the southern part of the coast. As for the  
1030 annual period, upward phase propagation is also evident for the semiannual and 120 day period, except at Cuddalore where  
1031 downward phase propagation is common during summer and winter months (Mukherjee et al., 2014; Mukhopadhyay et al.,  
1032 2020). Further, unlike annual and semiannual periods, the 120 day and intraseasonal variability decorrelate along the coast  
1033 indicating that these high frequencies are dominated by local responses rather than remote forcing (Mukherjee et al., 2018;  
1034 Mukhopadhyay et al., 2020a).

#### 1035 **4.4.1.3 Undercurrents**

1036 ADCP observations along the east coast of India suggest that during summer and winter, when the near-surface current is  
1037 shallow, the EICC often exhibits undercurrents along the continental slope. As the EICC is deeper in the north, the  
1038 undercurrent is observed at a depth of 100-150 m and can extend up to 700 m. However, in the south undercurrents are seen  
1039 at relatively shallow depths of about 70-75 m (Francis et al., 2020). Moreover, while these undercurrents are observed  
1040 throughout the coast, they are much more prominent and more frequent in the southernmost station of the coast, i.e. at  
1041 Cuddalore (Fig. 14, Mukherjee et al., 2014; Mukhopadhyay et al., 2020).

1042  
1043 **Figure 14: Circulation pattern in the southwestern Bay of Bengal at (a) surface (b) 200 m and (c) 1200 m on 15**  
1044 **November 2014. Vectors show the current direction, and overlaid is the current magnitude ( $\text{cm s}^{-1}$ ). Note that the**  
1045 **scales of current vectors and color bar are different at each subplot. Blue circle (red triangle) represents the location**  
1046 **of ADCP deployed on the shelf (slope) off Cuddalore. Dashed black line represents the  $12^\circ\text{N}$  latitude. Continuous**  
1047 **gray lines represent the 100 m and 1000 m bathymetric contours. Rectangular box (magenta) indicates the subsurface**  
1048 **eddy near the shelf break. (d) Cross-shore structure of alongshore currents across  $12^\circ\text{N}$ . Dashed black vertical line**  
1049 **shows the core of the undercurrent, and red (blue) vertical lines shows the location of ADCP mooring on the slope**  
1050 **(shelf). Inset plot is the zoomed view of shelf break region indicated by green box (Reproduced from Francis et al.,**  
1051 **2020).**

1052 The prominent upward phase propagation of the annual signal in the subsurface layers, particularly in the southern stations,  
1053 suggests downward propagation of energy and is thereby attributed as one of the main causes of the undercurrents

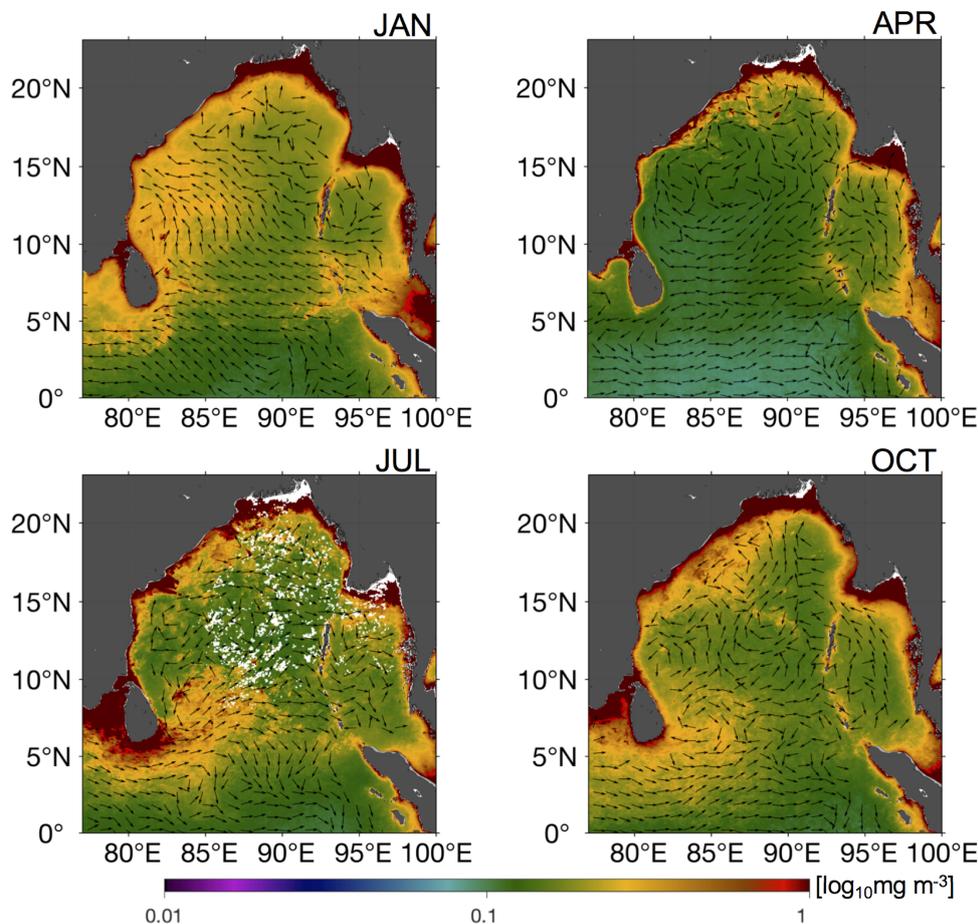

1054 (Mukherjee et al., 2014). A recent modelling study suggests that the wintertime undercurrent off Cuddalore consists of two  
1055 separate subsurface anticyclonic eddy circulations: a shallow small scale circulation at a depth range of 100-200 m and a  
1056 broader and deep flow below 500 m depth off the continental slope (Francis et al., 2020). The shallow subsurface  
1057 anticyclonic eddy was found to spin off from the zonal shear of the mean near-surface EICC along the shelf break (Fig. 14).  
1058 These eddies exhibit high frequency fluctuations and have 20-30 km length scales. Since the zonal share of the EICC is  
1059 primarily linked to the strength of the EICC itself, the variability and strength of this undercurrent is also linked with the  
1060 EICC.

#### 1061 4.4.1.4 Role of EICC in salt transport

1062 The EICC starts flowing southward north of 15°N as early as June (Fig. 10a) and eventually develops into a strong coastal  
1063 current during the winter monsoon (November through January) that extends all the way south of Sri Lanka and connects  
1064 the northernmost part of the bay, where large amounts of freshwater are discharged by the Indian river system, with the  
1065 Arabian Sea (AS; Fig. 4, Fig. 13). For this reason, the EICC is regarded as one of the possible pathways responsible for the  
1066 exchange of salt between the AS and the BoB (Hormann et al. 2019), along with the SMC (Fig. 10a; Jensen, 2001; Jensen  
1067 et al., 2016; Vinayachandran et al., 2013, 2018; Webber et al., 2018), which transports saline water north into the BoB  
1068 during June-September. Some of this saline water is transported directly around the tip of India (Fig. 10a), yet there is also  
1069 a role for transport along the equator from the western tropical Indian Ocean and the western AS (Sanchez-Franks et al.,  
1070 2019). In February, the off-shore current south of Sri Lanka is still flowing westward into the AS but the EICC north of  
1071 10°N starts flowing northward, reaches its maximum strength in April and stops south of 10°N by June, joining the offshore  
1072 limb of a cyclonic circulation further north that fills the northern Bay from June through August.

#### 1073 4.4.1.5 Sri Lanka Dome

1074 The Sri Lanka Dome (Vinayachandran et al. 1999; Schott and McCreary, 2001; Wijesekera et. al, 2016, Cullen and Shroyer,  
1075 2019) is mainly visible as a closed anticyclonic (clockwise) eddy in the near-surface geostrophic current velocity field  
1076 starting in May and lasting through October (Fig. 15c). It is a recurring upwelling dome that forms east of Sri Lanka between  
1077 5-10°N, 83-87°E. The SLD is embedded within the Southwest Monsoon Current (SMC) system (Gadgil, 2003) enhances  
1078 the SMC exchange from the Arabian Sea to the Bay of Bengal (Anutaliya et al., 2017). Upwelling associated with the SLD  
1079 influences the vertical exchange of water properties, enhances biological productivity, and cools sea surface temperature  
1080 (SST) which affects local atmospheric convection (Vinayachandran et al., 2004; de Vos et al., 2014).

1081

1082 **Figure 15: Climatology (2002–2018) of chlorophyll-a concentrations (colormap) and current velocities (arrows) in**  
1083 **the Bay of Bengal for (a) January (b) April (c) July (d) October. Chlorophyll climatology was obtained from the**  
1084 **MODIS-Aqua product and current velocities were obtained from the third-degree Ocean Surface Current Analysis**  
1085 **Real-time (OSCAR) product.**

#### 1086 4.4.1.6 Biogeochemical Variability

1087 In the Bay of Bengal, large inputs of freshwater from rivers give rise to enhanced stratification that inhibits upwelling and  
1088 wind-mixing and therefore nutrient enrichment of surface waters (Kumar et al., 2002; Vinayachandran et al., 2002;  
1089 Madhupratap et al., 2003; Vinayachandran, 2009). Nonetheless, increased productivity is observed along the coast primarily  
1090 in association with riverine nutrient inputs (Vinayachandran, 2009). These nutrients stimulate diatom blooms (Sasamal et  
1091 al., 2005) that give rise to significant increases in Chl-*a* concentration ( $\sim 30\text{--}100\text{ mgChla m}^{-2}$ ) and production ( $\sim 0.55\text{--}1\text{ gC}$   
1092  $\text{m}^{-2}\text{ d}^{-1}$ ) near the coast (Gomes et al., 2000; Fig. 15). This high Chl-*a* river water flows either along the coast or offshore, up

1093 to several hundred kilometers, depending on the coastal current pattern (Vinayachandran, 2009). Along the Indian coast,  
1094 the flow of Chl-*a*-rich water is determined by the EICC, which flows northward during the spring intermonsoon period and  
1095 Southwest Monsoon and southward during the autumn intermonsoon and Northeast Monsoon (Fig. 15 ). When the EICC  
1096 meanders seaward from the Indian coast, it leads to offshore increases in high chlorophyll water. It should also be noted  
1097 that during the spring intermonsoon and Southwest Monsoon the northward-flowing EICC is upwelling favorable, which  
1098 may contribute to increases in Chl-*a* concentration and primary production along the Indian coast (Hood et al., 2017)

1099

1100 In addition, elevated productivity is observed further offshore in the southwestern part of the Bay of Bengal during the  
1101 Northeast Monsoon (Vinayachandran and Mathew, 2003; Vinayachandran, 2009). Modeling studies suggest that these  
1102 elevated surface Chl-*a* concentrations are caused by wind-driven entrainment, not only of subsurface nutrients, but also of  
1103 phytoplankton from the subsurface chl<sub>a</sub> maximum that is present during the autumn intermonsoon period (Vinayachandran  
1104 et al., 2005). In contrast, productivity near the coast is suppressed during the Northeast Monsoon when the EICC flows  
1105 equatorward (Fig. 14). Presumably, this is due to a combination of the downwelling-favorable currents and winds. However,  
1106 primary production over the shelf in the northern part of the Bay increases during the Northeast Monsoon (Gomes et al.,  
1107 2000; Fig. 15 ), possibly due to river nutrient inputs (Vinayachandran, 2009) and / or wind-stress and buoyancy-driven  
1108 nutrient entrainment as is observed in the northern Arabian Sea during the Northeast Monsoon (Wiggert et al., 2000; 2005;  
1109 Hood et al., 2017).

1110

1111 Subsurface Chl-*a* maxima are observed in the Bay of Bengal developing during all seasons whenever and wherever wind  
1112 forcing and/or currents are insufficiently strong to upwell or entrain them into the surface layer (Sarma and Aswanikumar,  
1113 1991; Murty et al., 2000; Sarjini and Sarma, 2001; Kumar et al., 2007). During the intermonsoon periods the Bay of Bengal  
1114 transitions to more oligotrophic conditions with relatively low surface chlorophyll concentrations ( $< 0.6 \text{ mg/m}^3$ ; Fig. 15)  
1115 and production rates ( $< 700 \text{ mgC m}^{-2} \text{ d}^{-1}$ ; see Fig. 6 in Hood et al., 2017). *Trichodesmium erythraeum* blooms have been  
1116 observed during the intermonsoon periods along with high abundances of *Synechococcus* and heterotrophic dinoflagellates  
1117 (Sarjini and Sarma, 2001; Jyothibabu et al., 2008). In offshore waters subsurface chlorophyll maxima are generally located  
1118 between 40 and 70m in autumn and 60 and 90m in spring (Kumar et al., 2007). These deep Chl-*a* maxima tend to shoal  
1119 near the coast (Sarma and Aswanikumar, 1991; Murty et al., 2000) and their depth and chlorophyll concentrations are  
1120 strongly influenced by eddies (Kumar et al., 2007).

1121

1122 Strong upwelling also occurs along the southern coast of Sri Lanka during the Southwest Monsoon (Vinayachandran, 2004;  
1123 2009; de Vos et al., 2014). Satellite SST and chlorophyll images reveal dramatic eastward advection of cool ( $< 28^\circ \text{ C}$ )  
1124 chlorophyll rich upwelled water by the SMC (Vinayachandran, 2004; 2009; de Vos et al., 2014). Chlorophyll-rich waters  
1125 from the southwestern coast of India are also advected by the SMC towards Sri Lanka during the Southwest Monsoon  
1126 (Vinayachandran, 2004; 2009; Strutton et al., 2015). Surface chlorophyll concentrations and rates of primary production

1127 along the southern coast of Sri Lanka can exceed  $10 \text{ mgChla m}^{-3}$  (de Vos et al., 2014) and  $1000 \text{ mgC m}^{-2} \text{ d}^{-1}$  (see Fig. 6 in  
1128 Hood et al., 2017), respectively, during the Southwest Monsoon, compared to much lower concentrations and rates during  
1129 the Northeast Monsoon when the NMC flows westward (de Vos et al., 2014; Hood et al., 2017). Vinayachandran (2004;  
1130 2009) attribute the productivity response during the Southwest Monsoon to nutrient enrichment from coastal upwelling  
1131 driven by monsoon winds. Presumably, these high chlorophyll concentrations and production rates are associated with  
1132 diatom blooms. This elevated productivity extends to the east of Sri Lanka during the peak of the Southwest Monsoon  
1133 (Vinayachandran et al., 1999; Vinayachandran, 2004; 2009). This eastward extension into the southern Bay of Bengal  
1134 occurs along the path of the SMC (Vinayachandran et al., 1999) and is associated with upward Ekman pumping east of Sri  
1135 Lanka. This Ekman pumping also leads to the formation of the aforementioned Sri Lanka Dome (Vinayachandran and  
1136 Yamagata, 1998).

1137

#### 1138 **4.4.2 Arabian Sea**

1139 As for the Bay of Bengal (BoB), the Arabian Sea (AS) near surface circulation is also driven primarily by the seasonally  
1140 reversing monsoon winds. The AS is connected to the BoB through the passage between the southern tip of India and the  
1141 equatorial wave guide, and to the southern hemisphere by the cross equatorial flow via the Somali current system. The  
1142 Somali current (Fig. 10) forms one of the western boundary currents of the AS. Another major boundary current system is  
1143 along the west coast of India, the WICC (Fig. 10), which transports heat and salt from the northern Arabian Sea to the BoB,  
1144 and vice-versa. Recent observations (Chatterjee et al., 2012) and modelling studies (Shankar et al., 2015; Vijith et al., 2016)  
1145 indicate that the northern extent of the WICC reaches up to  $20^{\circ}\text{N}$  during the winter monsoon, carrying fresher BoB water to  
1146 the northern latitudes and modulating the wintertime convection there. In this section we will first discuss some recent  
1147 developments of the Somali current system and then the WICC.

##### 1148 **4.4.2.1 Somali current System**

1149 The Somali Current is a seasonally reversing western boundary current and is often composed of discontinuous non-linear  
1150 eddy driven flows. During summer it flows poleward and the upwelling here is nearly as large as for the eastern boundary  
1151 upwelling regimes of the Pacific and Atlantic Oceans (See Schott and McCreary, 2001 for a detailed review). Unfortunately,  
1152 owing to the piracy issue, direct in-situ observations are very rare in this region and mostly date back to the early 1960's  
1153 and 1970's. Hence, the scientific community has mostly relied on numerical model simulations to enhance understanding  
1154 of this region over the last few decades.

1155 Recent modelling studies suggest that during the summer monsoon, unlike other western boundary currents, the Somali  
1156 Current system can be divided into three dynamically distinctive regions (Wang et al., 2018; Chatterjee et al., 2019): northern  
1157 (north of  $8^{\circ}\text{N}$ ), central ( $3\text{-}8^{\circ}\text{N}$ ) and the southern (south of  $3^{\circ}\text{N}$ ) part. The northern and southern parts are driven by the large

1158 anti-cyclonic gyres called the Great Whirl (GW) and the southern Gyre (SG), respectively (Fig. 10a). Local southwesterly  
1159 alongshore winds known as the Findlater Jet (Findlater, 1969) drives Ekman transport all along the Somali coast (Schott  
1160 and McCreary, 2001) with varied magnitude which is strongest in the southern part, and significantly weakens northward  
1161 (Chatterjee et al., 2019). The wind stress forcing leads to Ekman Pumping in the central Arabian Sea, setting up a bowl-  
1162 shaped mixed layer and warming at the 100 m level. Ekman downwelling velocities are strongest in the northern part and  
1163 likely contributes to the formation of the Great Whirl front which upwells cold subsurface water in this part of the coast.  
1164 The central part, in contrast, is mainly driven by the local winds and remotely forced Rossby waves. In fact, the annual  
1165 Rossby waves radiated out of the southwestern coast of Sri Lanka seem to play a major role in the reversal of currents to  
1166 poleward flow in the northern part of the Somalia coast as early as in mid April. This reversal likely initiates the generation  
1167 of the Great Whirl (Beal and Donohue, 2013; Vic et al., 2014), a month in advance of the strong northeastward Findlater Jet  
1168 commences along the Somali coast. As the monsoon progresses, these downwelling favourable Rossby waves oppose the  
1169 coastal Ekman upwelling and thereby start to weaken the upwelling all along the coast. Moreover, as the alongshore winds  
1170 peak, this favours enhanced mixing at the bottom of the mixed layer, which deepens the thermocline further. This process  
1171 is more conspicuous in the central part of the coast, where the depth of the 22°C isotherm deepens by about 30-40 m from  
1172 June to August (Chatterjee et al., 2019). By this time, the upwelling becomes limited to the northern part of the coast along  
1173 the Great Whirl front of the Somali region.

#### 1174 **4.4.2.2 West India Coastal Current (WICC)**

1175 The WICC reverses its direction annually: flowing equatorward (upwelling favourable) during the summer monsoon (i.e.  
1176 May to September; Fig. 10a) and poleward (downwelling favourable) during the winter monsoon (i.e. November to  
1177 February; Fig. 10b). The equatorward flow during the summer characterises the WICC as a classical eastern boundary  
1178 current (Shetye and Shenoi, 1988). Interestingly, as the monthly mean alongshore winds off the west coast of India are  
1179 unidirectional (equatorward) throughout the year, the surface currents flow against the winds during the winter driven by  
1180 coastally-trapped Kelvin waves forced remotely in the BoB and along the east coast of India (McCreary et al., 1993; Shankar  
1181 and Shetye, 1997; Shankar et al., 2002; Suresh et al., 2016). Recent observations based on satellite data and alongshore  
1182 ADCP moorings reveal strong interannual variability of this seasonal cycle. Vialard et al. (2009), based on a short ADCP  
1183 record during 2006-2008, reported an absence of seasonal cycle off Goa and they attributed this absence to the radiation of  
1184 Rossby waves south of the critical latitude. However, later as the longer record of ADCP data became available, a clear  
1185 seasonal cycle in the WICC became evident with weaker amplitudes in the south, stronger poleward (Amol et al., 2014).

1186 The WICC also shows significant intraseasonal variability at times, particularly during boreal winter, exhibiting much  
1187 stronger energy in the intraseasonal band than in the seasonal band (Vialard et al., 2009; Amol et al., 2014). Unlike the  
1188 seasonal cycle, intraseasonal variability is stronger in the south and weakens poleward. Vialard et al. (2009) attributed this  
1189 intraseasonal variability to the atmospheric MJO forcing. Recently, a modelling study suggested that interception of the

1190 intraseasonal equatorial Rossby waves by the southern tip of India and Sri Lanka excites coastal Kelvin waves which  
1191 contribute significantly (~60–70%) to the intraseasonal variability along the west coast (Suresh et al., 2013). A satellite sea  
1192 level study by Dhage and Sturb (2016) confirmed the model-based findings of Suresh et al. (2013) and revealed that large  
1193 scale winds from the south of India and Sri Lanka also contribute to the coastal signals along the west coast of India.

1194 Another striking feature observed in these ADCP data is the clear signature of upward phase propagation in all timescales  
1195 during both monsoon seasons. This upward phase propagation is more conspicuous for the seasonal period than for the  
1196 intraseasonal. As a result, the phase of the surface currents often tends to be opposite that in the subsurface layers (Amol et  
1197 al., 2014). Moreover, it is found that the strength of this undercurrent intensifies northward along the west coast with  
1198 strongest undercurrent off Mumbai and the weakest off Kanyakumari (southernmost point of Indian mainland), indicating  
1199 a possible downward propagation of energy along the ray path as suggested earlier by Nethery and Shankar (2007). Since  
1200 the ray angle ( $\theta$ ) depends on the frequency ( $\sigma$ ) and stratification ( $N_b$ ) according to  $\theta = \sigma / N_b$  (McCreary, 1984; Nethery and  
1201 Shankar, 2007) the angle the beam makes from the horizontal is deeper for the intraseasonal band than for the seasonal. As  
1202 a result, intraseasonal beams propagate energy deeper layers into the water column. Therefore, while the WICC shows some  
1203 coherence along the coast in the seasonal time scale, it completely decorrelates horizontally for the intraseasonal period.

#### 1204 4.4.2.3 Biogeochemical Variability

1205 During the southwest monsoon, the western side of the northern Indian Ocean transitions to a eutrophic coastal upwelling  
1206 system in response to the upwelling favorable winds and currents (Wiggert et al., 2005; Hood et al., 2017 and references  
1207 cited therein; Fig. 5[1] ; see also Figs. 5 and 6 in Hood et al., 2017). These changes can be seen in ocean color data as  
1208 substantial increases in chl $a$  concentrations along the coasts of Somalia, Yemen and Oman (e.g., Brock and McClain, 1992;  
1209 Banse and English, 2000; Kumar et al., 2000; Lierheimer and Banse, 2002; Wiggert et al., 2005; George et al., 2013; Hood  
1210 et al., 2017). Chlorophyll- $a$  concentrations in the western Arabian Sea can exceed 40 mgChl $a$  m $^{-2}$  during the southwest  
1211 monsoon with production rates  $> 2.5$  gC m $^{-2}$ d $^{-1}$  (Marra et al. 1998; and see also Fig. 6 in Hood et al., 2017). However, the  
1212 environmental conditions vary significantly between the eutrophic coastal zones to the west and the oligotrophic open ocean  
1213 waters offshore that are influenced by wind-curl induced downwelling to the southwest of the Findlater Jet (Lee et al., 2000).  
1214 The surface nitrate and Chl- $a$  concentrations decline dramatically from  $> 10$  to  $< 0.02$   $\mu$ M and from  $> 1.0$  to  $< 0.2$  mgChl $a$   
1215 m $^{-3}$ , respectively, from the west coast to open ocean in the Arabian Sea (Brown et al., 1999; Wiggert et al., 2005; Hood et  
1216 al., 2017). In general, the phytoplankton community structure transitions to larger cells (diatoms) during the southwest  
1217 monsoon in the western Arabian Sea (Brown et al., 1999; Tarran et al., 1999; Shalapyonok et al., 2001). However, small  
1218 primary producers remain important, even in areas strongly influenced by coastal upwelling (Brown et al., 1999). In  
1219 contrast, during the oligotrophic spring and fall intermonsoon periods, surface waters in the western Arabian Sea are  
1220 dominated by picoplankton (Garrison et al., 2000). Subsurface Chl- $a$  maxima are observed between 40 and 140 meters in  
1221 the central southeastern Arabian Sea during all seasons (Gunderson et al., 1998; Goericke et al., 2000; Ravichandran et al.,

1222 2012), at times occurring in layers below the oxyclines of the oxygen minimum zone (Georricke et al., 2000). These features  
1223 are strongly influenced by mesoscale features (Gundersen et al., 1998).

1224

1225 During the southwest monsoon off Oman and Somalia, the presence of the topographically-locked eddies generate strong  
1226 offshore flows that advect high nutrient, high Chl-*a* concentrations and coastal phytoplankton communities hundreds of  
1227 kilometers offshore (Keen et al., 1997; Latasa and Bidigare, 1998; Manghnani et al., 1998; Gundersen et al., 1998; Hitchcock  
1228 et al., 2000; Lee et al., 2000; Kim et al., 2001). These advective effects can be seen, for example, in association with the  
1229 Great Whirl off the coast of northern Somalia (Hitchcock et al., 2000) and in the filaments that develop off the Arabian  
1230 Peninsula during the southwest monsoon (Wiggert et al. 2005; Hood et al., 2017). In contrast, during the northeast monsoon,  
1231 the circulation and winds transition to downwelling favourable. During the northeast monsoon, cold dry northeasterly winds  
1232 from southern China and the Tibetan Plateau flow across the northern Arabian Sea. The sheer from these winds, combined  
1233 with surface cooling and buoyancy-driven convection, drive mixing and entrainment of nutrients that, in turn, promote  
1234 modest increases in chlorophyll and primary production over the northern Arabian Sea (Wiggert et al., 2000; Wiggert et al.,  
1235 2005; Fig. 5[2] ; see also Figs. 5 and 6 in Hood et al., 2017). These increases in Chl-*a* have been associated with increased  
1236 diatom abundance (Banse and McClain, 1986; Sawant and Madhupratap, 1996). In the last decade, however, there appears  
1237 to have been a shift in the composition of winter phytoplankton blooms in the northern and central Arabian Sea from diatom  
1238 dominance to blooms of a large, green mixotrophic dinoflagellate, *Noctiluca scintillans* (Gomes et al., 2014; Goes et al.,  
1239 2020).

1240

1241 During the southwest monsoon, the upwelling-favorable WICC induces upwelling along the west coast of India, which  
1242 increases Chl-*a* concentrations by more than 70% compared to the central Arabian Sea (Kumar et al., 2000; Naqvi et al.,  
1243 2000; Luis and Kawamura, 2004; Hood et al., 2017). However, these increases in Chl-*a* and their offshore extent are modest  
1244 compared to the western Arabian Sea (Fig. 5[3] and see also Fig. 5 in Hood et al., 2017). The increased Chl-*a* concentrations  
1245 near the coast are associated with increases in diatom abundance (Sawant and Madhupratap, 1996). In contrast, during the  
1246 northeast monsoon the WICC is downwelling-favorable and tends to suppress primary production off the southwestern coast  
1247 of India. The depletion of nutrients in this region during the northeast monsoon coincides with blooms of *Trichodesmium*  
1248 and dinoflagellate species (Parab et al., 2006; Matondkar et al., 2007) resulting in the extremely high rates of nitrogen  
1249 fixation (Gandhi et al., 2011, Kumar et al., 2017). However, as discussed above, further north and offshore, nutrient  
1250 entrainment enhances phytoplankton biomass and primary production during the northeast monsoon (Wiggert et al., 2000;  
1251 McCreary et al., 2001; Luis and Kawamura, 2004; Gomes et al., 2014; Goes et al., 2020; Fig. 5[4] ). Near-surface Chl-*a* and  
1252 primary production off the west coast of India (estimated from satellite ocean color measurements) increases from ~9 to 24  
1253 mgChl *a* m<sup>-2</sup> and from ~1 to 2.25 g C m<sup>-2</sup> d<sup>-1</sup>, respectively, from winter to the summer monsoon (Luis and Kawamura, 2004;  
1254 Fig. 5[5] and see also Figs. 5 and 6 in Hood et al., 2017). The elevated productivity during the southwest monsoon is

1255 modulated by the aforementioned coastal Kelvin waves that originate from the Bay of Bengal and propagate along the West  
1256 Indian Shelf, modifying circulation patterns and upwelling (Luis and Kawamura, 2004).

1257

1258 Satellite ocean color observations suggest that Chl-*a* concentrations remain low all year-round in the Laccadive Sea in spite  
1259 of the transition from upwelling circulations (anti-cyclonic) during the southwest monsoon to downwelling circulations  
1260 (cyclonic) during the northeast monsoon (Lierheimer and Banse, 2002; Fig. 5[6] ). This suggests that the upwelling-  
1261 enhanced productivity off the west coast of India during the southwest monsoon is largely restricted to the coastal zone.  
1262 There are, however, sporadic zonal increases in Chl-*a* concentration that extend into the Laccadive Sea (Lierheimer and  
1263 Banse, 2002). It is not known whether or not there are cryptic subsurface phytoplankton blooms during the southwest  
1264 monsoon associated with the Laccadive Low.

## 1265 **5 Inter-ocean exchange**

### 1266 **5.1 Indonesian Throughflow**

#### 1267 **5.1.1 General features**

1268 The Indonesian Throughflow (ITF) transfers low-salinity tropical waters from the Pacific to the Indian Ocean via the  
1269 Indonesian seas (Fig. 10). The ITF is the only tropical oceanic pathway that links ocean basins and plays an important role  
1270 in the global ocean circulation and climate system (Sprintall et al., 2014; 2019). The simultaneous measurements in the exit  
1271 channels of the ITF from the International Nusantara Stratification and Transport (INSTANT) program during 2004-2006  
1272 (Gordon et al., 2008; Sprintall et al., 2009) suggested that the ITF has a mean transport of 15 Sv into the Indian Ocean. The  
1273 ITF pathway is composed of many narrow channels within the Indonesian seas, among which about 80% of the total ITF is  
1274 through the Makassar Strait (Fig. 10, Gordon et al., 2008, 2010). The remaining passages include the Maluku Sea, Lifamatola  
1275 Passage, Karimata Strait and Sibutu Passage (Fang et al., 2010; Gordon et al., 2012; Susanto et al., 2013).

#### 1276 **5.1.2 Variability, dynamics and influence**

1277 The interannual variability of the ITF is mainly dictated by the ENSO-related wind forcing through the Pacific waveguide  
1278 (e.g., Hu and Sprintall, 2016), but the IOD occasionally offsets the Pacific ENSO influences through the Indian Ocean wind  
1279 variability and Indian Ocean waveguide (Sprintall and Révelard, 2014; Liu et al. 2015; Feng et al., 2018). Strong wind  
1280 forcing over the equatorial Indian Ocean triggers equatorial Kelvin waves and influences the ITF variability on intraseasonal,  
1281 semi-annual and interannual time scales (Drushka et al., 2010; Pujiana et al., 2013; Shinoda et al., 2012). Kelvin waves  
1282 through the Indian Ocean waveguide are suggested to influence the interannual variability in the tropical Pacific Ocean  
1283 (Yuan et al., 2013).

1284 The ENSO cycle also influences the outflowing ITF transport through the salinity effect in the downstream buoyant pool,  
1285 which contributes to about 36% of the total interannual variation (Hu and Sprintall, 2016). Fresh anomalies in the buoyant  
1286 pool can be as large as 0.2 in practical salinity averaged over the upper 180 m of the water column (Phillips et al. 2005).  
1287 Such salinity anomalies can further strengthen the volume transport of the LC (Feng et al., 2015a). The Inter-decadal Pacific  
1288 Oscillation/Pacific Decadal Oscillation (IPO/PDO), through modulations of decadal wind stress in the tropical Pacific has  
1289 also directly influenced the strength of the ITF (Feng et al., 2011; Hu et al., 2015; Mayer et al., 2018), as well as its heat and  
1290 freshwater transports, causing changes in upper ocean heat content variations in the southern Indian Ocean (Feng et al.,  
1291 2010; Schwarzkopf and Böning, 2011; Nidheesh et al., 2013; Sprintall, 2014; Lee et al., 2015; Nieves et al., 2015; Du et al.,  
1292 2015; Ummenhofer et al., 2017). During, the negative IPO phase, such as the climate change hiatus period in 1998-2012,  
1293 enhanced trade winds in the Pacific strengthened the ITF volume and heat transport into the Indian Ocean, driving a rapid  
1294 warming trend in the Southern Indian Ocean (England et al., 2014; Nieves et al., 2015; Lee et al., 2015; Liu et al., 2015,  
1295 Zhang et al., 2018). However, contributions from air-sea exchanges (Jin et al. 2018a,b) have also been suggested.  
1296 Furthermore, using a combination of theory, ocean reanalyses, OGCM simulations, and coupled climate model simulations,  
1297 Jin et al. (2018a,b) found eastern and western Indian Ocean heat content to be affected by remote Pacific forcing through  
1298 two distinct mechanisms via oceanic influences transmitted through the ITF and through the atmospheric bridge,  
1299 respectively. The intensified freshwater input within the Maritime Continent during the past decade is found to strengthen  
1300 the ITF and its heat and freshwater transports into the Indian Ocean, causing significant warming and freshening trends and  
1301 accelerated sea-level rise in the eastern Indian Ocean (Hu and Sprintall, 2017a, 2017b; Zhang et al., 2018; Jyoti et al., 2019).  
1302 The decadal enhancement of the ITF transport has built up upper ocean heat content anomalies in the southeast Indian Ocean  
1303 and increased the likelihood of marine heatwaves off the west coast of Australia (Feng et al., 2015b; Section 6.4).

## 1304 **5.2 Agulhas Leakage**

### 1305 **5.2.1 General features**

1306 The Agulhas Current, the western boundary current of the southern Indian Ocean gyre, (Fig. 10), flows southward along the  
1307 South African coastline. At the tip of Africa, the current retroflects with most of the flow heading eastwards, on the northern  
1308 edge of the ACC, and recirculates back into the Indian Ocean. Around 20-30% of the Agulhas Current enters the Atlantic  
1309 Ocean as Agulhas leakage in the form of Agulhas rings and cyclones (van Sebille, 2010a). Agulhas leakage estimates are  
1310 sensitive to the definition used to calculate the leakage, ranging roughly between 10 and 20 Sv (van Sebille et al., 2010b;  
1311 Beron-Vera et al., 2013; Cheng et al., 2016; Holton et al., 2017). Bars et al. (2014) proposed an algorithm to measure  
1312 Agulhas leakage anomalies using absolute dynamic topography data from satellites.

1313 The division of flow between Agulhas Leakage and Agulhas retroflexion can be influenced by the upstream Agulhas  
1314 Current. In a Lagrangian particle tracking experiment, van Sebille et al. (2009) found that a weaker Agulhas Current,

1315 detaching farther downstream and generating anti-cyclonic vorticity, potentially leads to more Agulhas leakage and larger  
1316 Indian-Atlantic inter-ocean exchange. However, eddy-resolving model results suggest that as model resolution increases,  
1317 the sensitivity of the leakage to Agulhas Current transport anomalies is reduced (Loveday et al., 2014). In addition, the ITF  
1318 potentially influences the Agulhas leakage (Le Bars et al., 2013), as model outputs suggest that the Indian Ocean contributes  
1319 12.6 Sv, half of which is from the ITF, to the Agulhas leakage (Durgadoo et al., 2017).

## 1320 **5.2.2 Variability, dynamics and influence on climate**

1321 The magnitude of the Agulhas leakage is controlled by wind forcing including the trade winds and the Southern Hemisphere  
1322 Westerlies (e.g., Durgadoo et al., 2013). The poleward shift in the Southern Hemisphere westerlies associated with  
1323 anthropogenic forcing induced a clear increase in the Agulhas leakage during 1995-2004 as shown in numerical simulations  
1324 (Biaostoch et al., 2009; Biaostoch and Böning, 2013). Increased wind stress curl in the South Indian Ocean associated with the  
1325 southward shift of westerlies led to significant warming in the Agulhas Current system since the 1980's (Rouault et al.,  
1326 2009); however further work showed that this is due to an increase in eddies leading to a broadening of the current as  
1327 opposed to intensification (Beal and Elipot, 2016). Given the non-linear nature of Agulhas leakage and the lack and  
1328 difficulties of observing it, combined with ocean model biases in the region, quantifying Agulhas leakage is very challenging  
1329 (Holton et al., 2017). At seasonal time scales, the Agulhas leakage variability is controlled by eddies, however recent studies  
1330 have shown that eddies might not contribute as significantly to leakage as was thought and the non-eddy leakage transport  
1331 is likely to be constrained by large-scale forcing at longer time scales (e.g., Cheng et al., 2018). A recent study shows that  
1332 the subsurface signal from the ENSO cycle influences the Agulhas leakage through Rossby waves with a time lag of 2 years  
1333 (Paris et al., 2018).

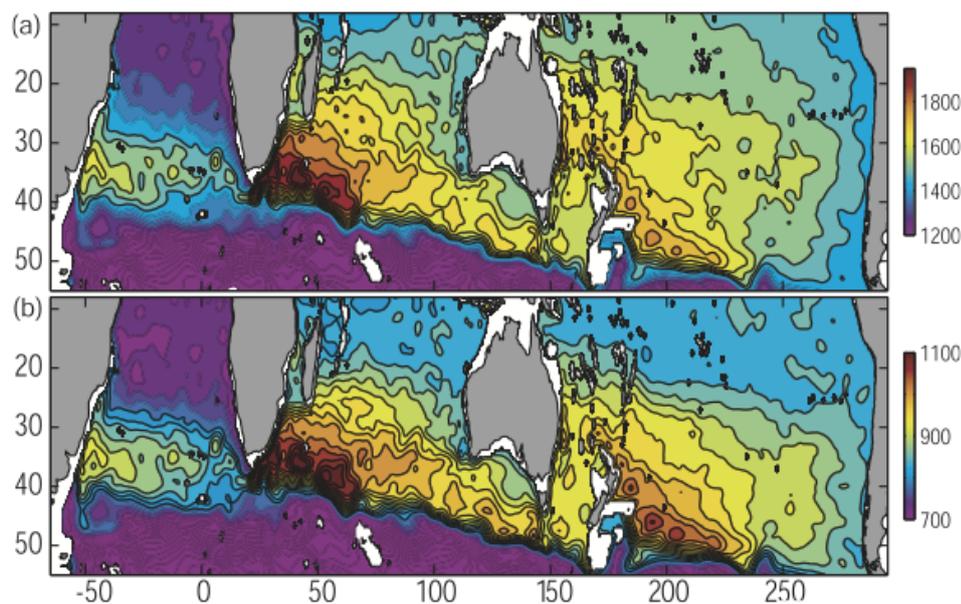

1334 The Agulhas leakage carries warm and saline water from the Indo-Pacific Ocean into the Atlantic Ocean. The Agulhas  
1335 leakage has been suggested to influence the Atlantic Meridional Overturning Circulation strength (AMOC; Beal et al.  
1336 2011; Weijer and van Sebille, 2014, Biaostoch et al. 2015) and modify the AMOC convective stability (e.g., Haarsma et al.,  
1337 2011; Caley et al., 2012; Castellanos et al., 2017). It is suggested that the increases in the Agulhas leakage due to  
1338 anthropogenic warming during the past decades would act to strengthen the Atlantic overturning circulation (e.g., Beal et  
1339 al., 2011).

1340 The Agulhas leakage is an important source of decadal variability in the AMOC through Rossby waves (Biaostoch et al.,  
1341 2008; 2015). Source waters from the Agulhas Current take more than 4 years and mostly one to four decades to end in the  
1342 North Atlantic Ocean (van Sebille et al., 2011; Rühls et al., 2013). The increased Agulhas leakage during 1995-2004 has  
1343 contributed to the salinification of the South Atlantic thermocline waters (Biaostoch et al., 2009). Hindcast experiments  
1344 suggest that the Agulhas leakage increases by about 45% during 1960s-2000s and leads to the observed warming trend in  
1345 the upper tropical Atlantic Ocean (Lübbecke et al., 2015).

### 1346 5.3 Supergyre connection to the South Pacific

1347 The extreme strong westerly wind stress in the Southern Hemisphere gives rise to a wide and energetic subtropical supergyre  
1348 (Figure 16) that connects three ocean basins, the Southern Hemisphere supergyre (e.g., Ridgway and Dunn, 2007; Speich et  
1349 al., 2007; Cessi, 2019). The supergyre is the subtropical gyre of the southern hemisphere. As such, its flow is primarily  
1350 determined by the westward integration of wind stress curl from the eastern boundaries as determined by Sverdrup dynamics.  
1351 The latitudinal position of the Subtropical Front associated with the supergyre is found to be controlled by strong bottom  
1352 pressure torque due to the interaction between the ACC and the ocean floor topography (De Boer et al., 2013). Not much is  
1353 known about the decadal and multidecadal variability of the supergyre. According to one analysis on SODA (Duan et al.,  
1354 2013), the water masses in the supergyre became cooler and fresher and shifted southward by about  $2.5^\circ$  due to changes in  
1355 the basin-scale wind forcing during 1958–2007.

1356  
1357 **Figure 16: The interbasin supergyre system for the Pacific and Indian Oceans as shown by the depth-integrated**  
1358 **steric height (a)  $P_{0/2000}$ , and (b)  $P_{400/2000}$ , derived from the CARS climatological temperature and salinity fields. The**  
1359 **contour interval in (a) is  $50 \text{ m}^2$  and in (b) is  $25 \text{ m}^2$ . Taken from Ridgway and Dunn 2007.**

1360 The regional ocean circulation system including the ITF and Leeuwin Current are thought to be dynamically connected to  
1361 the supergyre, which connects the Indian and Pacific Oceans by the Tasman Gateway and the Indonesian seas (Lambert et  
1362 al., 2016). Lagrangian experiments indicate the existence of a “superconvergent”, which is a surface convergent pathway  
1363 connecting the subtropical South Indian and South Pacific Ocean, and confirmed that current variability in the Southern  
1364 Hemisphere supergyre is essential to sustaining the superconvergent (Maes et al., 2018).

1365 A recent study using altimeter observations shows a clear strengthening of the Southern Hemisphere supergyre in all three  
1366 oceans since 1993 as indicated in the large trends of sea surface height and their contrast. Argo observations and ECCO  
1367 assimilations suggest that the strengthening extends to deeper than 2000 m (Qu et al., 2019). Qu et al. (2019) found that the  
1368 spin-up of the Southern Hemisphere supergyre is attributed to the poleward shift and strengthening of westerly winds that  
1369 are linked to an increasingly positive southern annular mode.

1370 Although the near-surface circulation is eastward across the SIO, there are subsurface westward flows beneath (Schott and  
1371 McCreary 2001, Domingues et al. 2007, Furue et al. 2017), and the depth-integrated circulation reveals the westward return  
1372 flow of the equatorward side of the anti-clockwise subtropical gyre. The southern Indian Ocean hosts a “supergyre” (Speich  
1373 et al. 2007, Ridgway and Dunn 2007). In Figure 16, the southern side of the Indian Ocean subtropical gyre extends eastward  
1374 south of Australia to connect with the western Pacific subtropical gyre. The return flow is accomplished via a pathway that  
1375 includes the East Australian Current, the South Pacific’s western boundary flow; the Tasman Leakage, a westward flow  
1376 south of Tasmania that carries Pacific Ocean water back to the Indian Ocean (distinct from the Flinders Current that hugs  
1377 the continental slope, Duran et al 2020; Section 4.2.4); and northwestward flow in the eastern Indian Ocean to close the  
1378 circulation.

#### 1379 **5.4 Roles of salinity in inter-ocean exchange**

1380 Oceanic salinity is one of the basic variables that determines the oceanic stratification, sea level change and climate change  
1381 (e.g., Llovel and Lee, 2015; Kido and Tozuka, 2017; Sprintall et al., 2019). However, the role of salinity in ocean circulation  
1382 has been largely underestimated until the recent decade when the comprehensive suite of *in situ* observations of subsurface  
1383 and surface salinity from Argo and satellite salinity missions became available. These new observations revolutionize our  
1384 understanding of the influence of salinity on ocean circulation and dynamics (Vinogradova et al. 2019, and references  
1385 therein).

1386  
1387 Four major processes control the salinity in the Indian Ocean: net air-sea fluxes (evaporation minus precipitation), freshwater  
1388 inflow from large rivers in the Bay of Bengal, inflow of relatively fresh waters from the Pacific Ocean through the Indonesian  
1389 Throughflow straits, and inflow of saltier waters from the Red Sea and the Persian/Arabian Gulf. These different drivers  
1390 combine to give the Indian Ocean salinity its unique flavour: a strong east-west gradient in the North Indian Ocean (salty in  
1391 the Arabian Sea and fresh in the Bay of Bengal) and strong north-south gradients in the South Indian Ocean (fresh in the  
1392 tropics, and salty in the subtropics) (Fig. 4).

1393  
1394 As the new observations are revealing, salinity is a crucial variable to understand Indian Ocean dynamics. For instance,  
1395 salinity has strong ties with the Indian Ocean Dipole (e.g., Du and Zhang, 2015; Durand et al., 2013; Grunseich et al., 2011;  
1396 Kido and Tozuka, 2017; Nyadjro and Subrahmanyam, 2014; Zhang et al. 2016), the EGC (Menezes et al., 2013), LC

1397 transport, Ningaloo Niño and marine heatwaves off western Australia (e.g., Feng et al., 2015a), and the El Niño/La Niña  
1398 climate mode (e.g., Hu and Sprintall, 2016, Zhang et al., 2016). Salinity plays an essential role in the dynamics of the  
1399 seasonal Wyrki Jets in the equatorial zone (e.g., Masson et al., 2003), extra-equatorial Rossby waves (Heffner et al., 2008;  
1400 Menezes et al., 2014b; Vargas-Hernandez et al., 2015; Banks et al., 2016), Madden-Julian and Intraseasonal Oscillations  
1401 (e.g., Grunseinch et al., 2013; Guan et al., 2014; Subrahmanyam et al., 2018), barrier-layer dynamics (e.g., Drushka et al.,  
1402 2014; Felton et al., 2014), and the North Indian Ocean (e.g., D’Addezio et al., 2015, Fournier et al., 2017; Mahadevan et  
1403 al., 2016; Nyadjro et al., 2011, 2012, 2013; Wilson and Riser, 2016; Spiro Jaeger and Mahadevan, 2018), and salinity  
1404 controls the sea level change in the southeastern Indian Ocean (Llovel and Lee, 2015).

1405

1406 Salinity variability within the Indonesian Seas has been shown to control the transport of the ITF. Andersson and Stigebrandt  
1407 (2005) proposed that a downstream buoyancy pool in the outflowing ITF region acts to regulate the ITF transport. Gordon  
1408 et al. (2003, 2012) pointed out that low salinity surface water from the South China Sea is drawn into the Java Sea. Combined  
1409 with the monsoonal precipitation over the Maritime Continent and seasonal monsoon winds, this freshwater plug contributes  
1410 to the seasonal fluctuation of the Makassar Strait Throughflow transport and inhibits the inflow of tropical Pacific surface  
1411 water from the Mindanao Current (e.g., Gordon et al., 2012; Lee et al., 2019). Recently, Hu and Sprintall (2016) found that  
1412 about 36% of the interannual ITF transport is attributable to the salinity effect associated with freshwater input anomalies  
1413 due to the ENSO cycle. A significant strengthening of the ITF transport in the 2000s has given rise to a subsequent warming  
1414 and freshening of the eastern Indian Ocean (e.g., Hu and Sprintall, 2017a, 2017b, Section 6.1). Recently, Jyoti et al. (2019)  
1415 further examined the salinity effect in the ITF transport following Hu and Sprintall (2016) and found that the unprecedented  
1416 sea-level rise in the southern Indian Ocean since the beginning of the 21st Century is attributed to the accelerated heat and  
1417 freshwater intrusion by the ITF.

1418

## 1419 **6 Modes of Interannual Climate Variability in the Indian Ocean**

### 1420 **6.1 ENSO teleconnection and the Indian Ocean Basin mode**

1421 ENSO influences the Indian Ocean circulation through the Pacific-to-Indian Ocean oceanic waveguide and the atmospheric  
1422 teleconnection. Through the atmospheric bridge, El Niño conditions in the Pacific induce an anticyclonic wind anomaly  
1423 pattern in the southeast Indian Ocean (Xie et al., 2002), whereas La Niña induces a cyclonic wind anomaly pattern (Feng et  
1424 al., 2013). The ENSO teleconnection also drives SST variability over the western Indian Ocean during ENSO development.  
1425 The tropical Indian Ocean experiences prolonged warming (cooling) that peaks in the following boreal spring and persists  
1426 into boreal summer, after the decay of El Niño (La Niña) events, the so-called Indian Ocean Basin (IOB) mode (Yang et al.,  
1427 2007). The westward propagating Rossby waves induced by ENSO may also help sustain the warming (cooling) of the

1428 tropical Indian Ocean (Xie et al., 2002), fueled by regional air-sea coupling (Du et al., 2009). The IOB warming has a  
1429 capacitor effect for El Niño to influence boreal summer climate in the northwest Pacific (Xie et al., 2009). The relationship  
1430 between ENSO and IOB evolves on a decadal time scale, and the persistent IOB warming after El Niño has been evident  
1431 since the 1970s (Xie et al., 2010). Based on the CMIP5 multi-model experiments, the IOB warming tends to persist longer  
1432 after the El Niño events under global warming scenarios (Zheng et al., 2013).

1433 The ITF transport is stronger after a La Niña and weaker after an El Niño (Meyers, 1996; England and Huang, 2005). The  
1434 ITF variability lags ENSO by 8-9-months, found in ocean model results (England and Huang, 2005) and derived from the  
1435 geostrophic transport across an Australia-Indonesia XBT section (Liu et al., 2015). The variability of the ITF transport drives  
1436 sea level and upper ocean heat content anomalies in the southeast Indian Ocean. Through the waveguide, ENSO has a direct  
1437 influence on the strength of the Leeuwin Current (Section 4.2.4), with a stronger poleward volume and heat transport during  
1438 a La Niña event (Feng et al., 2008). A stronger Leeuwin Current during La Niña events leads to greater baroclinic instability  
1439 of the current and enhanced generation of eddies that leads to interannual variability of the eddy kinetic energy in the  
1440 southeast Indian Ocean (Feng et al., 2005; Zheng et al., 2018). The increase of the ITF transport and enhancement of rainfall  
1441 in the Indonesian Seas during strong La Niña events can drive up to 0.2-0.3 psu freshening anomalies in the upper southeast  
1442 Indian Ocean (Phillips et al., 2005; Feng et al., 2015a; Hu and Sprintall, 2017a), which may have a compound effect in  
1443 accelerating the Leeuwin Current (Feng et al., 2015a). Both ENSO and the IOD (see Section 6.2) influence the ITF and thus  
1444 the exchange of heat from the Pacific into the Indian Ocean, but in concurrent IOD and ENSO events it appears that the  
1445 influence from the IOD dominates (Sprintall and Revelard, 2014).

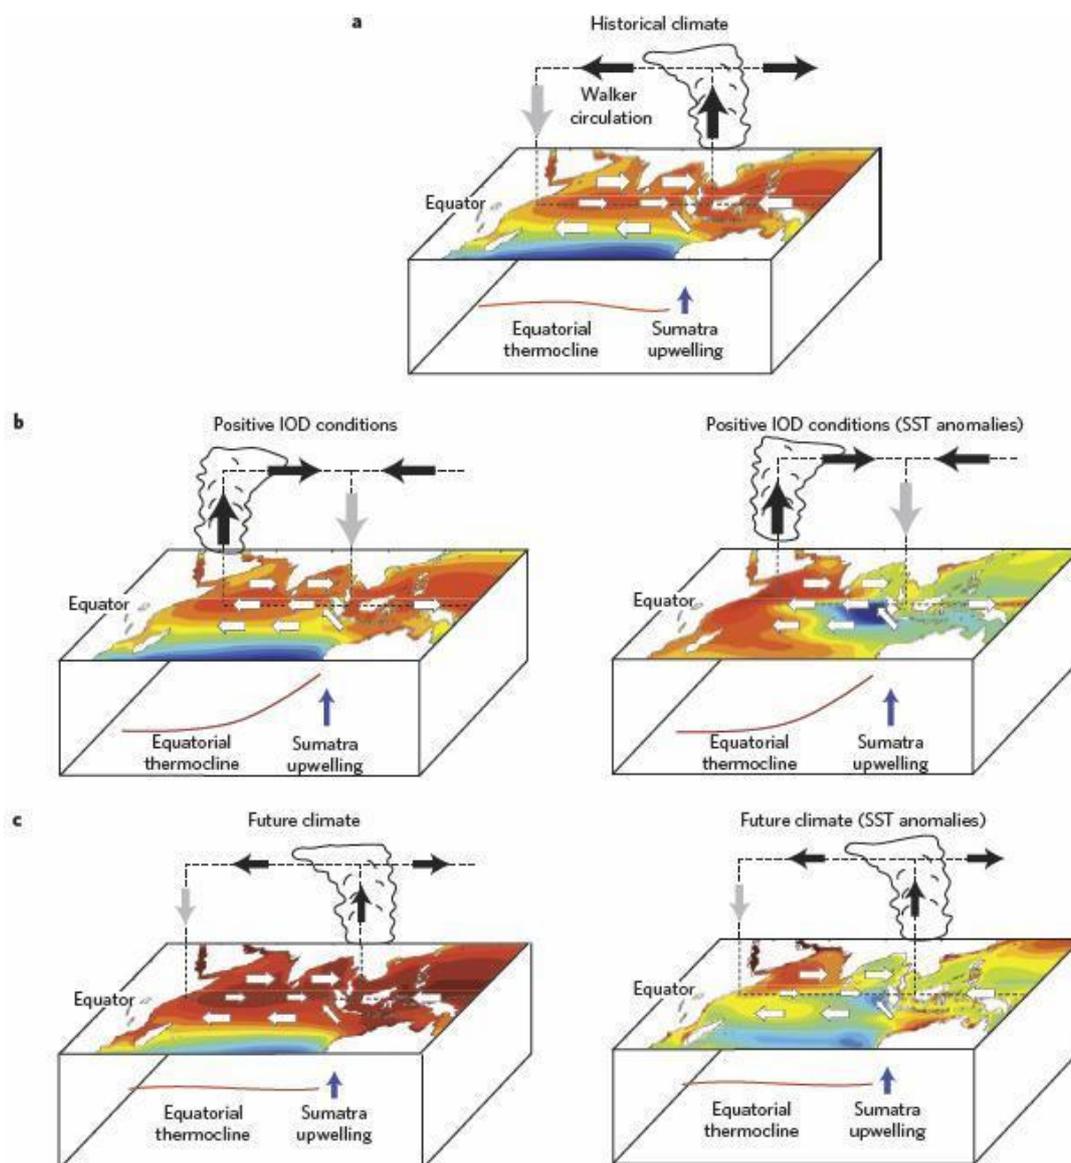

1446 Due to the opposing effects of the winds and dissipation, ENSO induced sea level and upper ocean heat content anomalies  
1447 in the southeast Indian Ocean do not propagate far into the western Indian Ocean; instead, wind anomalies generate sea level  
1448 and heat content anomalies of opposite signs in the western Indian Ocean through Rossby wave propagations (Masumoto  
1449 and Meyers, 1998; Xie et al., 2002; Zhuang et al., 2013; Ma et al., 2019). Thus, the joint forcing of the oceanic waveguide  
1450 and atmospheric teleconnection results in variations of meridional overturning circulation and heat transport in the Indian  
1451 Ocean on a multi-year time scale, in phase with the ITF variability (Ma et al., 2019).

## 1452 **6.2 The Indian Ocean Dipole**

1453 There is increasing evidence that positive IOD events are more frequent and intense during the 20th century (e.g., Abram et  
1454 al., 2008; Cai et al., 2013; Abram et al., 2020a,b; and references therein). A rare occurrence of three consecutive positive  
1455 IOD events took place in 2006-2008 (Cai et al., 2009b). The skewness towards more positive and fewer negative IOD events  
1456 (Cai et al., 2009a) is due potentially to an anthropogenically-driven shoaling thermocline in the eastern Indian Ocean (Cai  
1457 et al., 2008). The three consecutive positive IOD events rarely occurred in Coupled Model Intercomparison phase 5 (CMIP5)  
1458 models and the more recent frequent occurrence was consistent with regional Indo-Pacific Walker circulation trends (Cai et

1459 al., 2009c,d). An anthropogenic contribution was proposed since positive IOD events became more frequent over the period  
1460 1950–1999 in the CMIP5 models. Projected mean-state changes in the Indian Ocean with stronger easterly winds and a  
1461 shoaling thermocline in the southeast Indian Ocean during austral spring favour positive IOD development, with a reduction  
1462 in skewness between positive and negative IOD events likely (Cai et al., 2013; Figure 17), and a three-fold increase in  
1463 frequency of extreme positive IOD events by 2100 compared to the previous century (Cai et al., 2014a). Based on a  
1464 millennial IOD reconstruction from corals, extreme positive IOD events, as were observed in 1997 and 2019, were  
1465 historically rare (Abram et al., 2020b). In the reconstruction, only ten extreme positive IOD events occurred and yet four  
1466 events occurred in the last 60 years (Abram et al., 2020b). The increase in event frequency and intensity highlights the need  
1467 to improve preparedness in regions affected by IOD events and minimize future climate risks.

1477 While model simulations and paleo proxy records suggest changes in the frequency and magnitude of IOD events in a  
1478 warming climate, there is less observational evidence from other sources. Given the short observational record in the Indian  
1479 Ocean, the role of decadal to multi-decadal variability across the broader Indo-Pacific region has recently emerged as a  
1480 compounding factor: the number and frequency of IOD events have been observed to vary on decadal timescales. Decadal  
1481 variations in SST featuring an IOD-like out-of-phase pattern between the western and eastern tropical Indian Ocean have  
1482 been linked to the PDO (Krishnamurthy and Krishnamurthy, 2016) or IPO (Dong et al., 2016). A combination of processes  
1483 transmits the signal from the Pacific to the Indian Ocean through both the atmospheric and oceanic bridges, leading to  
1484 variations in the subsurface temperature structure in the Indian Ocean (Zhou et al., 2017; Jin et al., 2018a). Decadal  
1485 modulations of the background state of the eastern Indian Ocean thermocline depth can thus pre-condition the Indian Ocean  
1486 to more or less IOD events (Annamalai et al., 2005). Consequently, positive IOD events were unusually common in the  
1487 1960s and 1990s with a relatively shallow eastern Indian Ocean thermocline, while the deeper thermocline in the 1970s and  
1488 1980s was associated with frequent negative IOD and rare positive IOD events (Ummerhofer et al., 2017). The Indian  
1489 Ocean stands out as a region with high skill in decadal predictions (Guemas et al., 2013) and improved understanding of  
1490 decadal modulation of IOD events can aid in decadal prediction efforts for the Indian Ocean region.

1491 The relationship between ENSO and the IOD has been subject to ongoing debate. Recent research has shown that around  
1492 two-thirds of IOD variability arises as a remote response to ENSO (Stuecker et al., 2017; Yang et al., 2015), with the  
1493 remaining variability being independent of ENSO. Stuecker et al. (2017) argue that the ENSO-driven IOD can be seen as a  
1494 combination of remotely driven wind and heat flux anomalies modulated by seasonally-varying Bjerknes feedback in the  
1495 Indian Ocean. Further, they suggest that the ENSO-independent IOD events arise out of white noise atmospheric forcing  
1496 coupled to these feedbacks (Stuecker et al., 2017). Variability internal to the Indian Ocean basin and unrelated to ENSO,  
1497 arising from ocean-atmosphere feedback processes, does however modulate the evolution of IOD events and can lead to  
1498 early termination of IOD events; as a result, including internal variability improves the predictability of the IOD (Yang et  
1499 al., 2015). The relationship between ENSO and the IOD is not only one-way: IOD events have also been shown to influence  
1500 the development of ENSO in the following year (Izumo et al., 2010; Wang et al., 2019; Cai et al., 2019; and references  
1501 therein).

1502 Different types of IOD events have been described, each with distinct evolution and regional impacts (Du et al., 2013; Endo  
1503 and Tozuka, 2016). Du et al. (2013) distinguished three types of IOD events according to the timing of their peak amplitude  
1504 and overall duration: ‘unseasonable’ events that develop and mature mostly within June-August (JJA), ‘normal’ events that  
1505 develop and mature mostly within September-November (SON), and ‘prolonged’ events that develop in JJA and mature in  
1506 SON, with the latter two described as the canonical IOD events (Du et al., 2013). The unseasonable IOD events have only

1507 been observed since the mid-1970s and have been suggested to be a response to the rapidly warming Indian Ocean SST and  
1508 a weakened Walker circulation during austral winter (Du et al., 2013). The seasonal evolution and type of ENSO also seems  
1509 to play a role in determining the IOD evolution and type, with atmospheric influences transmitted through variations in the  
1510 Walker Circulation and oceanic ones through anomalous oceanic Rossby waves affecting timing and evolution of IOD  
1511 events, especially during their developing phase (Guo et al., 2015; Zhang et al. 2015; Fan et al., 2017). However, Sun et al.  
1512 (2015) suggested more IOD events independent of ENSO since the 1980s, along with higher correlations between the IOD  
1513 and Indian summer monsoon activity, likely due to mean-state change in the tropical Indian Ocean due to weaker equatorial  
1514 westerlies. The relationship between ENSO and the IOD has weakened in recent decades, linked to changes in the ENSO-  
1515 induced rainfall anomalies over the Maritime Continent (Han et al., 2017).

1516 Recent advances in understanding variability and change in IOD characteristics have implications for the relationships  
1517 between SST and regional rainfall patterns in Indian Ocean rim countries. For example, different types of IOD events exhibit  
1518 distinct regional impacts, with only the canonical events associated with enhanced rainfall over East Africa due to the low-  
1519 level moisture convergence over the region (Endo and Tozuka, 2016). The effect of Indian Ocean SST on East African  
1520 rainfall is most pronounced during the short rains (September-November), though Williams and Funk (2011) argued that  
1521 warming Indian Ocean SST in recent decades were also associated with reduced long rains for the March-June season in  
1522 Ethiopia and Kenya. Changes in the tropical atmospheric circulation across the Indo-Pacific on multi-decadal timescales  
1523 (Vecchi and Soden, 2007; L'Heureux et al., 2013) have further implications for the relationship between Indian Ocean SST  
1524 and regional rainfall: When the Pacific Walker cell weakened and the Indian Ocean one strengthened post-1961, the East  
1525 African short rains became more variable and wetter (Nicholson, 2015). Similarly, Manatsa and Behera (2013) described  
1526 an epochal strengthening in the relationship between the IOD and East African rainfall post-1961, with 73% of short rain  
1527 variability in East Africa explained by the IOD, up from 50% in previous decades. After 1997, this increased further to 82%,  
1528 explaining spatially coherent events across the region and frequent rainfall extremes (Manatsa and Behera, 2013). Recent  
1529 observed and projected changes in frequency and intensity of IOD events highlight the increasing need for preparedness in  
1530 vulnerable regions affected by these events.

1531 IOD events are associated with distinct changes in primary productivity, as measured by chlorophyll. During positive IOD  
1532 events, increased chlorophyll indicative of phytoplankton blooms is apparent in the normally oligotrophic eastern Indian  
1533 Ocean in fall (Wiggert et al., 2009; Currie et al., 2013). Positive chlorophyll anomalies occur in the southeastern Bay of  
1534 Bengal in boreal winter, while negative anomalies are observed over much of the Arabian Sea and southern tip of India. In  
1535 a case study of the 2006 positive IOD event, Iskandar et al. (2010) using an eddy-resolving biophysical model found the  
1536 offshore chlorophyll signal in the southeastern Indian Ocean to be associated with regions of high eddy kinetic energy  
1537 implying that cyclonic eddies injected nutrient-rich water into the upper layer enabling the bloom. Currie et al. (2013)  
1538 emphasize the importance of assessing the relative contributions of IOD events and remote impacts from ENSO on primary  
1539 productivity in the Indian Ocean through their respective influence on upper-ocean properties for improved understanding

1540 and ultimately predictions of productivity, ecosystems, and fisheries within the basin. Little attention has been paid so far  
1541 to resultant effects of these blooms on biogeochemical cycling (Wiggert et al., 2009).

### 1542 **6.3 The subtropical Indian Ocean Dipole**

1543 The subtropical Indian Ocean Dipole (SIOD) is a climate mode in the southern Indian Ocean, which tends to arise and peak  
1544 in the austral summer (Behera and Yamagata, 2001). During the SIOD's positive phase, the climate mode has positive SST  
1545 anomalies in the southwestern Indian Ocean and negative SST anomalies in the northeastern region (Behera and Yamagata,  
1546 2001; Suzuki et al., 2004; Hermes and Reason, 2005). During the positive phase, enhanced precipitation occurs over  
1547 southern Africa (Behera and Yamagata 2001; Reason 2001, 2002). Recent studies have shown that the SIOD affects the  
1548 Indian summer monsoon rainfall (Terray et al., 2003), rainfall over southwestern Australia (England et al., 2006), and  
1549 tropical cyclone trajectories in the southern Indian Ocean (Ash and Matyas, 2012).

1550 Initially, SST anomalies associated with the SIOD were considered to be generated directly by latent heat flux anomalies  
1551 (Behera and Yamagata, 2001). However, recent studies (Morioka et al. 2010, 2012) based on a mixed layer heat budget  
1552 analysis revealed the importance of mixed layer depth anomalies generated by latent heat flux anomalies. Wind anomalies  
1553 associated with the anomalous Mascarene High suppress latent heat loss and shoal the mixed layer in the southwestern part,  
1554 while latent heat release is enhanced and the mixed layer deepens anomalously in the northeastern part (Morioka et al. 2010,  
1555 2012). With these changes in the upper ocean heat capacity, warming of the surface mixed layer by the climatological  
1556 shortwave radiation is enhanced in the southwestern part and becomes less effective in the northeastern part. As a result, the  
1557 dipole SST anomalies appear in the southern Indian Ocean.

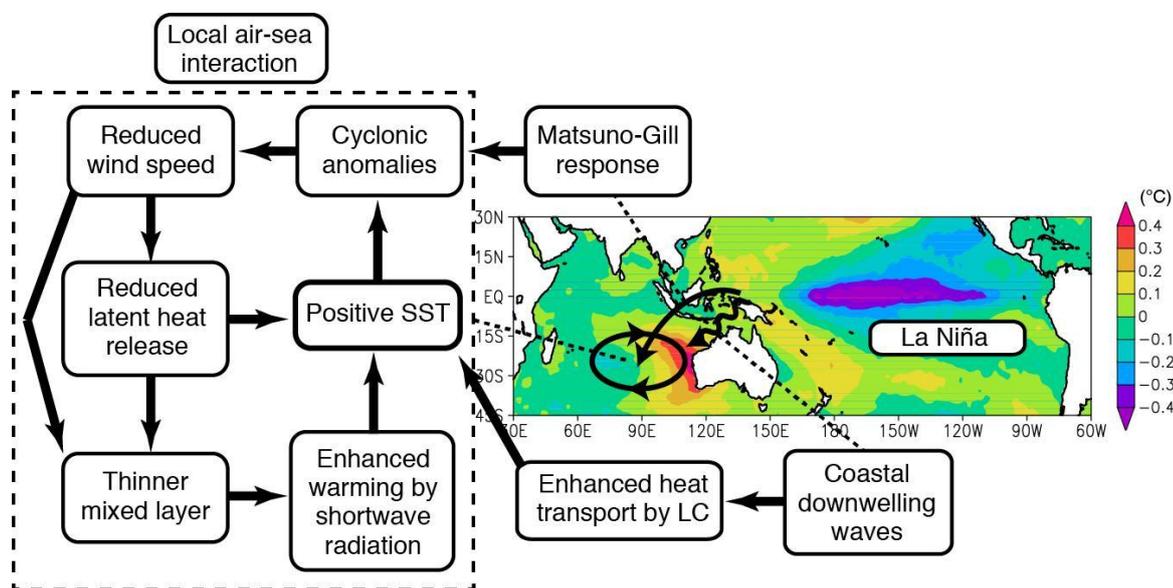

1558 Because the above mechanism operates more effectively as the thickness of the mixed layer becomes thinner, the return  
1559 period of the SIOD is becoming shorter associated with the shoaling trend of the mixed layer (Yamagami and Tozuka,  
1560 2015). Whether this mechanism is associated with decadal-to-interdecadal variations and/or global warming awaits further  
1561 study. Many coupled models are relatively successful in simulating the SIOD with some biases in the location and structure  
1562 of the SST anomaly (Kataoka et al., 2012). However, no study has examined if the SIOD is modulated by climate modes of  
1563 variability with decadal-to-interdecadal timescales or changes with global ocean warming.

### 1564 **6.4 Ningaloo Niño and marine heatwaves in the Indian Ocean**

1565 The Ningaloo Niño (Niña) phenomenon is an interannual climate mode associated with anomalously warm (cold) water in  
1566 the eastern Indian Ocean (Feng et al., 2013; see Figure 18). This mode is seasonally phase-locked, with a peak during austral  
1567 summer (Kataoka et al., 2014). The mode exerts significant impacts on rainfall over Australia (Kataoka et al., 2014) and  
1568 affects marine ecosystems and fisheries (e.g. Pearce et al. 2011). The phenomenon can alter biological productivity, with

1569 negative chlorophyll anomalies during Ningaloo Niño (Narayanasetti et al., 2016). Ningaloo Niños can develop in response  
 1570 to remote ENSO forcing from the western Pacific transmitted as a coastally trapped wave (Kataoka et al., 2014). During the  
 1571 La Niña events, high sea level anomalies propagate poleward along the west coast of Australia, intensifying the Leeuwin  
 1572 Current and causing poleward advection of heat and anomalously warm waters (e.g. Benthuisen et al., 2014; Section 4.2.4).  
 1573 Poleward transport of tropical, low salinity waters can further enhance the total geostrophic transport (Feng et al., 2015a).

1574

1575 **Figure 18: Schematic diagram illustrating generation mechanisms (i.e. local air-sea interaction, atmospheric**  
 1576 **teleconnection, and oceanic wave propagation) of the Ningaloo Niño. SST anomalies are regressed against the**  
 1577 **Ningaloo Niño Index to illustrate typical SST anomalies associated with the phenomenon.**

1578 Atmospheric teleconnection can further enhance the development of Ningaloo Niño. A reduction in southerly winds over  
 1579 the shelf, which would strengthen the Leeuwin Current, can arise through a Gill-type response with low sea level pressure  
 1580 anomalies in the southeast Indian Ocean owing to the Niño3.4 SST anomalies (Feng et al., 2013; Tozuka et al., 2014).  
 1581 Ningaloo Niños can arise from local air-sea interactions off western Australia, through the wind-evaporation-SST feedback  
 1582 during its initial stage (Marshall et al., 2015) and coastal SST-wind-Leeuwin Current (Bjerknes) feedback (Kataoka et al.  
 1583 2014). In the coastal feedback mechanism, positive SST anomalies lead to northerly alongshore wind anomalies and coastal  
 1584 downwelling anomalies, causing enhancement of the positive SST anomalies (Kataoka et al., 2014). During the Ningaloo  
 1585 Niño's development phase, estimates of air-sea heat flux contributions have been found to be dependent on products and  
 1586 their resolution and bulk flux algorithms (Feng and Shinoda, 2019). Since the late 1990s, Ningaloo Niño events have  
 1587 occurred more frequently (Feng et al., 2015b). This decadal increase is corroborated by coral proxy records of Leeuwin

1588 Current strength, with the most extreme SST anomalies associated with Ningaloo Niños occurring since 1980 (Zinke et al.,  
1589 2014).

1590 More generally, marine heatwaves refer to prolonged, extremely warm water events. Over the past decade, most studies on  
1591 marine heatwaves in the Indian Ocean have focused on the eastern sector of the Indian Ocean. Major events in the Indian  
1592 Ocean have been associated with phases of ENSO. Along the west coast of Australia, marine heatwaves have occurred  
1593 predominantly at subtropical reefs during La Niña events due to increased heat transport (Zhang et al., 2017). The term  
1594 “marine heatwave” was first coined owing to a +5°C warm water event in 2011 off Western Australia during a strong La  
1595 Niña (Pearce et al., 2011). The 2011 event was associated with the strongest recorded Leeuwin Current transport anomaly,  
1596 bringing warm tropical waters south, and was partly due to air-sea heat fluxes (Feng et al., 2013; Benthuisen et al., 2014).

1597 Across Australia’s northwestern shelf, marine heatwaves have been found to occur at tropical coral reefs from El Niño due  
1598 to solar radiation and a weakened monsoon (Zhang et al., 2017). During the strong El Niño of 2015-2016, the southeast  
1599 tropical Indian Ocean experienced the warmest and longest marine heatwave on record, with weakened monsoon activity  
1600 and anomalously high air-sea heat flux into the ocean (Benthuisen et al., 2018). The anomalously warm water conditions  
1601 persisted into winter, during one of the strongest negative IOD events (Benthuisen et al., 2018). The 2016 marine heatwave  
1602 was associated with coral bleaching spanning Australia’s inshore Kimberley region to remote coral reef atolls (Gilmour et  
1603 al., 2019). More broadly across the Indian Ocean during 2016, marine heatwaves have been studied in terms of their  
1604 ecological impacts, such as coral bleaching in the western Indian Ocean (e.g. Gudka et al., 2018), the Maldives (e.g. Ibrahim  
1605 et al., 2017) and consequences for fishes in the Chagos Archipelago (Taylor et al., 2019).

1606 Trends in marine heatwave metrics indicate widespread regions across the Indian Ocean where events have increased in  
1607 frequency, based on SST from 1982-2016, especially in the central and southwestern sectors (Oliver et al., 2018). Over the  
1608 same time period, the duration and intensity of marine heatwaves have increased (Oliver et al. 2018). Primary climate modes  
1609 of variability correlated with an increased occurrence of marine heatwaves include the following: (1) the positive phase of  
1610 the Dipole Mode Index for the northwestern sector, the tropical sector, and south to the Seychelles Islands, (2) the positive  
1611 phase of the Niño3.4 index for the south-central sector, and (3) the negative phase of the El Niño Modoki index, which  
1612 measures the strength of the Central Pacific ENSO, for the eastern Indian Ocean (Holbrook et al., 2019). While the marine  
1613 heatwaves in the eastern Indian Ocean have been well documented, there have been fewer studies into the physical  
1614 mechanisms causing marine heatwaves across the basin and other regions and less confidence, for example in the Bay of  
1615 Bengal, in the local processes causing reported events on a range of time scales (Holbrook et al. 2019). There are indications  
1616 that increased extremes in El Niño (Cai et al., 2014b) and La Niña events (Cai et al., 2015) due to mean ocean warming  
1617 trends increase the likelihood of marine heatwave occurrence in the southeast Indian Ocean (Zhang et al., 2017).

1618

## 1619 **7. Multiscale upper ocean processes in the Bay of Bengal**

1620 Reflective of its name, the Bay of Bengal is in many ways analogous to a large-scale estuary with seasonally reversing winds  
1621 and boundary currents that facilitate the transport, stirring, and mixing of water masses. To the north, the Ganga-  
1622 Brahmaputra-Meghna watershed delivers on average 1300 km<sup>3</sup> in annual runoff of freshwater with a seasonal peak in  
1623 discharge from July to September (Sengupta et al., 2006). During the southwest monsoon (boreal summer), the Summer  
1624 Monsoon Current (Fig. 10) flows eastward advecting high salinity waters from the Arabian Sea into the southern Bay of  
1625 Bengal, balancing the Bay's net outflow of freshwater. Instabilities and eddies result in mesoscale stirring of these different  
1626 water types and create a strongly filamented and complex near-surface thermohaline structure. Lateral and vertical gradients  
1627 in stratification are further modified by submesoscale processes, instabilities, and mixing. The resultant shallow stratification  
1628 allows for rapid coupling with the atmosphere. Collectively, these conditions present a natural laboratory to study multi-  
1629 scale mixing processes and their link to air-sea interaction. This section discusses new understanding of physical processes  
1630 in the Bay from the large-scale to sub-mesoscale and finally at the smallest mixing scales.

1631 Recent focus on the Bay of Bengal's upper ocean structure has been prompted by the need to understand atmosphere and  
1632 ocean coupling with the aim of ultimately informing monsoon forecasting efforts at the intraseasonal timescale and shorter.  
1633 Several bi-lateral international collaborations (Lucas et al., 2014; Wijesekera et al., 2016; Mahadevan et al., 2016;  
1634 Vinaychandran et al., 2018; Gordon et al., 2019, 2020) have collectively supported multiple field campaigns, beginning in  
1635 2013 and concluding in 2019, using a combination of shipboard, moored, and autonomous platforms. These atmospheric  
1636 and oceanic measurements have provided new insights into the BoB's structure and the processes that regulate that structure,  
1637 particularly at fine lateral scales (<5 km).

1638 Results from these combined efforts span from large-scales, e.g., the quantification of coastal transport along the Sri Lankan  
1639 coast (Lee et al., 2016) and the mesoscale stirring of freshwater (Sree Lekha et al., 2018), to intermediate scales, e.g., high-  
1640 resolution (order 100 m) frontal surveys that hint at the roles of submesoscale (Ramachandran et al., 2018) and non-  
1641 hydrostatic processes in setting stratification (Sarkar et al., 2016), to small-scales with direct measurements of microstructure  
1642 yielding new insights into the BoB's mixing regimes (Jinadasa et al., 2016; Thakur et al., 2019; Cherian et al. 2020).

### 1643 **7.1 The Bay's Forcing and Upper Ocean Structure**

1644 At the largest scales, the Bay is forced by air-sea fluxes of buoyancy and momentum, which are strongly modulated by the  
1645 monsoon and vice versa. Precipitation and multiple river systems, including the Ganga-Brahmaputra-Meghna system,  
1646 contribute to freshwater input that creates a barrier layer in the surface Bay of Bengal, which is strongest in the northern  
1647 Bay weakening toward the south. The Bay's stratification, in particular its barrier layer, is unique in how it impacts the  
1648 evolution of seasonal SST, in turn setting the lower boundary condition for the development of the monsoon (Li et al., 2017).

1649 For this reason, recent emphasis has been placed on understanding of processes determining the Bay's upper ocean salinity  
1650 and temperature structure.

1651 The monsoon cycle of surface forcing plays a first-order role in control of the Bay's upper ocean temperature structure.  
1652 Direct flux measurements are a critical component in our ability to accurately capture/represent and predict the magnitude  
1653 and variability of monsoon air-sea coupling. Recent studies have shown that of the air-sea heat flux terms, shortwave  
1654 radiation and latent heat flux are the largest drivers of variability to the total heat tendency. These variables are also those  
1655 which reanalysis products struggle most to accurately represent, showing biases up to  $75 \text{ W/m}^2$  (Sanchez-Franks et al.,  
1656 2018). High-quality air-sea surface flux measurements over the BoB historically have been limited to the few sites  
1657 maintained by the RAMA array (McPhaden et al., 2009). However, regional measurement efforts have expanded and  
1658 baseline surface measurements are now collected and sustained through India's National Institute of Ocean Technology's  
1659 met-ocean buoy program (Venkatesan et al., 2018), as well as the recent transition of an  $18^\circ\text{N}$  air-sea flux buoy from Woods  
1660 Hole Oceanographic Institution to Indian National Centre for Ocean Information Services (Weller et al., 2016).

1661 Precipitation and riverine discharge along the Bay's margins respectively contribute roughly 60% and 40% of the 0.14 Sv  
1662 net freshwater delivered to the Bay (Sengupta et al. 2006; Wilson and Riser, 2016). Precipitation peaks in early summer  
1663 (June) with a value near  $0.4 \text{ m month}^{-1}$ , while discharge peaks slightly later in summer (August) with a value near  $0.3 \text{ m}$   
1664  $\text{month}^{-1}$ . Evaporative loss (included in the net 0.14 Sv) is relatively steady throughout the year at  $0.1 \text{ m month}^{-1}$  (Wilson  
1665 and, Riser 2016). Estimates of river discharge from gauged sources are known to have uncertainties (underestimates) related  
1666 to unmonitored tributaries and streams. For large deltas, altimeter-based elevations offer a means of extrapolating gauge  
1667 data over space and time. Papa et al. (2010, 2012) applied such an approach to the Ganga-Brahmaputra River system for  
1668 the period 1998-2011. This time series allows for assessment of interannual variability over time ranges not spanned by  
1669 gauged efforts. Papa et al. (2012) note a  $12,500 \text{ m}^3/\text{s}$  standard deviation in interannual variability in the Ganga-Brahmaputra  
1670 discharge. Importantly, such data sets are also easily accessible by the general public, facilitating progress and understanding  
1671 by the scientific community.

1672 The Bay's upper ocean temperature and salinity structure is an integrated representation of the above summarized  
1673 sources/sinks of heat and freshwater, combined with the physical processes that redistribute these quantities. The  
1674 thermohaline structure of the Bay is remarkable in several regards—for shallow mixed layer depths ( $< 5 \text{ m}$ , Sengupta and  
1675 Ravichandran, 1998), for inversions of temperature (Shroyer et al., 2016, 2019; Thadathil et al. 2016), for large-scale  
1676 coherent layering that spans 100 kms (Shroyer et al., 2019), an active mesoscale field and the strong influence of river  
1677 discharge over the interior basin. The Bay's salinity stratification is a critical, if not dominant, contributor to the upper  
1678 ocean density stratification. It supports the formation of barrier layers that are frequently observed to be warmer than the  
1679 mixed layer thereby providing a substantial subsurface heat reservoir with the potential to modify air-sea interaction  
1680 (Girishkumar et al., 2011; Shroyer et al., 2016). For example, in conditions supportive of formation of a diurnal warm layer

1681 (low winds, strong insolation), subsurface turbulent fluxes can act to modulate the diurnal SST cycle by transporting  
1682 (typically) warm barrier layer waters into the mixed layer at night while still cooling the base of the diurnal warm layer  
1683 (DWL) during the day (Shroyer et al., 2016). A similar phenomenon, albeit on a much different scale, results with passage  
1684 of cyclones, which often show a salty wake even in the absence of a cool wake which is common for cyclones elsewhere  
1685 (for e.g. Chaudhuri et al. 2019, Qiu et al. 2019). Below, we review recent progress on understanding of processes that  
1686 determine the Bay's upper ocean thermohaline structure.

## 1687 **7.2 Lateral Processes**

### 1688 **7.2.1 Stirring from the Margins**

1689 The Bay of Bengal has an active mesoscale eddy field that stirs diverse source waters into the interior of the Bay of Bengal.  
1690 The origins of these source waters are the Arabian Sea waters to the west, the Ganga-Brahmaputra-Meghna at the northern  
1691 tip, Andaman Sea waters to the east, and Equatorial waters to the south. This stirring effectively contributes to a quasi-  
1692 stationary balance of the fresher waters from the north and the high salinity waters from the west and south over time. Lateral  
1693 advection is a fundamental contributor to the formation of the barrier layer (George et al., 2019) and the freshwater budget  
1694 of the Bay (e.g. Sree Lekha et al., 2018). In the northern Bay, the dispersal of water from the periphery into the interior  
1695 depends critically on mesoscale stirring and the time varying Ekman transport, as indicated from mooring (Sree Lekha et  
1696 al., 2018) and ship-based surveys (Shroyer et al., 2019), and constrained by modelling results (Sree Lekha et al., 2018).  
1697 Here, the advection of freshwater by the mesoscale stirring also plays an important role in determining SST over the northern  
1698 BoB (Buckley et al. 2020), as these waters are typically associated with relatively shallow mixed layers. In the southern  
1699 Bay, measurements have suggested the competing influences of mixing and advection of salty Arabian Sea water in the  
1700 erosion and reformation of the barrier layer during the southwest monsoon (George et al., 2019; Vinayachandran et al.,  
1701 2018). In particular, George et al. (2019) show that maintenance of the barrier layer and the associated maximum depth of  
1702 mixing was critically dependent on horizontal advection through its impact on stratification. Surface freshwater input also  
1703 has an impact on barrier layer evolution; several freshening events were captured at various stages of their seasonal evolution  
1704 in the southern Bay of Bengal in recent observations (Vinayachandran et al., 2018). These events play a significant role in  
1705 the formation of a thick barrier layer, showing that during the southwest monsoon the shoaling of the mixed layer in the  
1706 southern BoB has a similar magnitude and behaviour to that in the northern BoB (Vinayachandran et al., 2018).

### 1707 **7.2.2 Inter-basin exchange**

1708 Inter-basin exchange is critical to the Bay's salinity budget; since the Bay receives net freshwater input, this freshwater must  
1709 be balanced by salty water imported from either the Arabian Sea or the western equatorial Indian Ocean (Jensen et al., 2001;  
1710 Sanchez-Franks et al., 2019), and turbulent transport of salt into the fresh water layer is necessary to maintain the BoB's

1711 long-term salinity balance. Observations show that intrusion of high salinity water from the Arabian Sea enters the BoB  
1712 between 80°-90°E during the southwest monsoon, (e.g. Murty et al, 1992; Vinayachandran et al., 2013) and has been found  
1713 in several models (e.g. Vinayachandran et al., 1999; Han and McCreary, 2001 and Jensen, 2001). More recent observational  
1714 and modeling studies show that both lateral and vertical transfer of heat and salt occur at multiple space-time scales. Seasonal  
1715 currents play an important role in transporting heat and salt in and out of the BoB, but the role of mesoscale eddies on lateral  
1716 transports is not well known.

1717 Using unique year-long mixing measurements detailed in Section 7.3, Cherian et al. (2020) tentatively estimated a turbulent  
1718 salt flux of  $1.5 \times 10^{-6}$  psu m/s out of Arabian Sea water averaged between 85°E and 88.5°E at 8°N through the 34.75 psu  
1719 isohaline between August and January. Over those 6 months, this flux would increase the salinity of a 75m layer of water  
1720 by 0.3 psu, though much of this would be cancelled out by surface fluxes. The magnitude and timing of this salt flux roughly  
1721 match that necessary to restore the Bay's near-surface salinity after the large freshwater input in August as estimated by a  
1722 few modelling studies (Akhil et al., 2014; Benshila et al., 2014; Wilson and Riser, 2016). This is the first direct measurement  
1723 of turbulence that supports the hypothesis of intrusion of high salinity water from the Arabian Sea during the southwest  
1724 monsoon (Vinayachandran et al., 2013).

#### 1725 **7.2.2.1 Andaman Sea Exchange**

1726 The Irrawady river drains into the Andaman Sea, a marginal sea at the eastern edge of the Bay. Export from the Andaman  
1727 is then another source of freshwater for the Bay, particularly at intermediate densities ( $22-25 \text{ kg m}^{-3}$ ). A striking example of  
1728 the interaction between strong surface forcing and an anticyclonic eddy can be found in the fortuitous crossing of an  
1729 intrathermocline eddy (ITE) in 2013. The water mass characteristics clearly identify ITE waters from the Andaman Sea;  
1730 and, analysis of ancillary Argo data suggest a similar water type often penetrates westward into the Bay extending from the  
1731 three passages connecting the two basins (Gordon et al., 2017). While at the time of transit the observed ITE had a very  
1732 weak surface expression, a week prior to encountering the ITE a clear sea surface high ( $>10 \text{ cm}$ ) is evident in AVISO SSHA.  
1733 Tropical cyclone Lehar passed near the location of this sea surface high in the interim, and the working conjecture is that  
1734 the winds associated with Lehar were sufficient to modify a typical mode-1 anticyclone into the observed ITE.

#### 1735 **7.2.2.2 Arabian Sea Exchange**

1736 Near-surface exchange from the Arabian Sea into the Bay of Bengal is influenced by the Sri Lanka Dome (SLD), an  
1737 upwelling thermal dome that recurs seasonally within the SMC in the wind shadow of Sri Lanka (Vinayachandran and  
1738 Yamagata 1998, de Vos et al. 2014, Burns et al. 2017). The SLD has long been recognized as a prominent circulation feature  
1739 in the southwestern bay during the summer monsoon; and it has been noted as a region of enhanced productivity  
1740 (Vinayachandran et al., 2004, de Vos et al. 2014), cool SST (Burns et al. 2017), and consequently depressed convection  
1741 (Figure 15). The SLD displays pronounced interannual variability (Cullen and Shroyer 2019). In some years the SLD has a

1742 strong surface manifestation (amplitude of the low  $\sim 30$  cm) that persists well beyond the southwest monsoon; in other years  
1743 the SLD has a weak expression that is intermittent and short-lived ( $\sim 1$ -2 months). The SLD is not fixed in location despite  
1744 its strong association with the wind stress curl. Its position varies from year-to-year as well as over the course of one season.  
1745 Variations in its location and strength may influence the properties of waters entrained and upwelled within the SLD.

1746 At intermediate depths ( $< \sim 200$  m), the signature of the neighboring Arabian Sea is notable across much of the basin (Gordon  
1747 et al., 2016). During summer, Arabian Sea High Salinity Water (ASHSW; density near  $22$ - $24$  kg  $m^{-3}$ ) is carried/advected  
1748 into the Bay of Bengal as a ‘high salinity core’ via the Southwest Monsoon Current (SMC, Webber et al., 2018; Sanchez-  
1749 Franks et al., 2019) and then spread north along the bay’s central spine (Hormann et al., 2019). During this journey, salt is  
1750 mixed upward into the near-surface fresh layer (Cherian et al 2020; see Section 7.3 Vertical Mixing). Nearly two-year long  
1751 moored current observations in the southern BoB captured SMC and Northeast Monsoon Current, seasonally varying large  
1752 eddies including a cyclonic eddy, the SLD, and an anticyclonic eddy southeast of the SLD (Wijesekera et al. 2016c). These  
1753 observations revealed that the average transport over nearly a two year period into the BoB was about 2 Sv ( $1$  Sv =  $10^6$  m<sup>3</sup>  
1754 s<sup>-1</sup>) but likely exceeded 15 Sv during summer of 2014, which is consistent with the transport associated the SMC (e.g.,  
1755 Schott et al. 2009; Weber et al. 2018). The observations further indicate that the water exchange away from coastal  
1756 boundaries, in the interior of the BoB, may be largely influenced by the location and strength of the two eddies that modify  
1757 the path of the SMC. The strength and location of the SMC itself is dependent on a combination of local and remote forcing  
1758 (Webber et al., 2018).

1759 As discussed above several hypotheses have been suggested for cyclonic eddy (SLD) and anticyclonic eddy formation in  
1760 the southern BoB. It has been suggested that the cyclonic wind stress-curl over southwestern BoB generates the SLD  
1761 (McCreary et al., 1996; Vinayachandran and Yamagata 1998; Schott et al., 2001; Cullen and Shroyer 2019). Based on  
1762 numerical simulations, de Vos et al., (2014) argued that the separation of SMC from the (southern) boundary of Sri Lanka  
1763 may lead to SLD, where a cyclonic vorticity is generated by lateral frictional effects. A mechanism for the anticyclonic eddy  
1764 formation has been proposed by Vinayachandran and Yamagata (1998), where the interaction of the SMC with Rossby  
1765 waves arriving from the eastern boundary leads to the anticyclonic eddy. Pirro et al (2020a) proposed a new hypothesis  
1766 wherein the anticyclonic eddy is generated by topographically trapped Rossby wave response of the SMC to perturbations  
1767 by the Sri Lankan coast. They reported that observations of the size, location and origins of the SLD were broadly consistent  
1768 with their hypothesis, based on a laboratory experiment designed to mimic natural flow in the BoB by creating an eastward  
1769 jet (SMC) on a simulated  $\beta$  plane.

1770 High-resolution sampling of the interior BoB has provided a more detailed look at the lateral extent of typical ‘patches’ of  
1771 Arabian Sea water, which tend to remain well-defined over scales of 10-50 km, suggesting the importance of eddy activity  
1772 in exchange (Shroyer et al., 2019). While many studies have traced origins of ASHSW from the eastern Arabian Sea,  
1773 entering the Bay of Bengal directly via the southwest monsoon current (e.g., Jensen et al, 2016); a recent study suggests an

1774 equatorial pathway may also be relevant (Sanchez-Franks et al., 2019; see Equatorial Connections). Highly salty and highly  
1775 oxygenated waters from the Persian Gulf and the Red Sea have also been noted in the southern regions of the Bay of Bengal  
1776 (Jain et al., 2017). These waters are injected into the Bay of Bengal via current systems (equatorial and the southwest  
1777 monsoon current) with important repercussions for the oxygen concentrations of the Bay of Bengal oxygen minimum zone  
1778 (Sheehan et al., 2020).

1779 Velocity and hydrographic profiles from a shipboard survey in December 2013 combined with drifter observations, satellite  
1780 altimetry, global ocean nowcast/forecast products, and coupled model simulations were used to examine the circulation in  
1781 the southern Bay of Bengal during Northeast monsoon (Wijesekera et al. 2015). The observations captured the southward  
1782 flowing East India Coastal Current (EICC, e.g., Shetye et al. 1994) off southeast India and east of Sri Lanka. The EICC was  
1783 approximately 100 km wide, with speeds exceeding  $1 \text{ m s}^{-1}$  in the upper 75 m. East of the EICC, a subsurface-intensified  
1784 300-km-wide, northward current was observed, with maximum speeds as high as  $1 \text{ m s}^{-1}$  between 50 m and 75 m. The EICC  
1785 transported low-salinity water out of the bay and the subsurface northward flow carried high-salinity water into the bay  
1786 during typical northeast monsoon conditions (Wijesekera et al. 2015; Jensen et al. 2016).

### 1787 **7.2.3 Equatorial Connections**

1788 The Equatorial undercurrent (EUC) in the Indian ocean is seasonally variable. The summer–fall EUC tends to occur in the  
1789 western basin in most years but exhibits evident interannual variability in the eastern basin (Chen et al. 2015), with different  
1790 processes dominating its generation in the western and eastern basins. In the eastern basin reflected Rossby waves from the  
1791 eastern boundary play a crucial role in the EUC, whereas directly forced Kelvin and Rossby waves control the EUC in the  
1792 western basin.

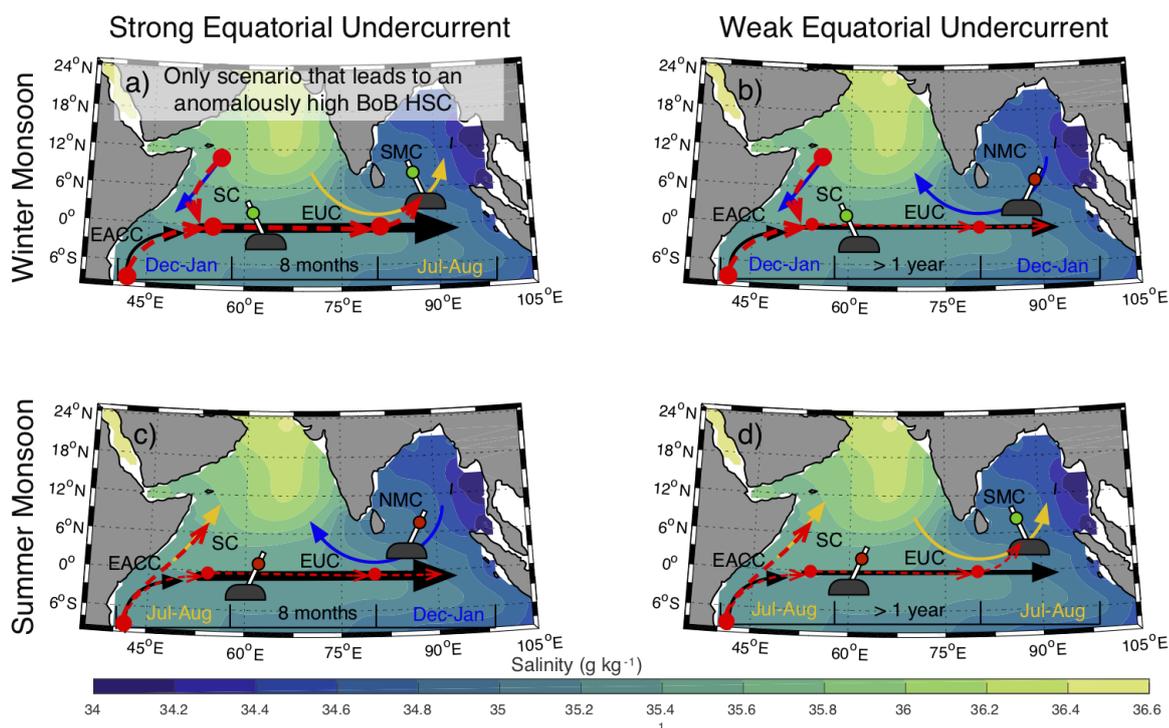

1793 Equatorial Kelvin waves, commonly interpreted as Wyrтки (1973) jets, propagate eastward along the equator during  
1794 April/May and September/October. Upon reflection from the IO eastern boundaries, energy of Wyrтки jets is reflected back  
1795 in part as long Rossby waves that disperse slowly during the following two months and reach the central-eastern BoB during  
1796 July-August (Han et al., 1999, 2001; Han, 2005; Nagura and McPhaden, 2010a). The remaining energy is partitioned into  
1797 two coastally-trapped Kelvin waves traveling poleward (Moore, 1968), which excite long Rossby waves propagating  
1798 westward. Therefore it is suggested that planetary waves driven by remote forcing from the interior IO contribute  
1799 significantly to the formation, strength and intensity of BOB circulation (Vinayachandran et al. 1998; Nagura and  
1800 McPhaden, 2010b; Chen, 2015). A subset of these planetary waves are the mainstay of intraseasonal oscillations (ISOs), a  
1801 sub-seasonal phenomenon of periods less than 120 days. The genesis of oceanic ISOs has been attributed to multiple  
1802 mechanisms: external forcing (e.g., atmospheric ISOs and Ekman pumping, e.g. Duncan and Han 2012) and internal  
1803 processes (upper ocean processes and instabilities e.g. Zhang et al. 2018).

1804

1805 Observations in the IO have captured a range of variabilities in the 30 – 120 days frequency band (e.g., Girishkumar et al.,  
 1806 2013), and past research has identified roughly three distinct ISO bands in the context of thermocline: 30-60 days, 60-90  
 1807 days, and 120 days (Han et al., 2001; Girishkumar et al., 2013). Pirro et al. (2020b) discussed interaction between 30-60 day  
 1808 ISOs and the SMC in the southern BoB using long-term moored observations. They estimated that the background mean  
 1809 flow acceleration resulting from the meridional divergence of wave momentum flux in the thermocline was about  $10^{-8} \text{ m s}^{-2}$ .  
 1810 As a result, within a wave period, ISOs can enhance the eastward flow in the thermocline by about 25%. The negative  
 1811 shear production computed for the same period consistent with this finding suggesting that the mean flow gained kinetic  
 1812 energy at the expense of the ISO band. The meridional heat-flux divergence was  $-10^{-7} \text{ °C s}^{-1}$  and has a tendency for cooling  
 1813 the thermocline by about  $0.5^\circ\text{C}$  when ISOs are active (Pirro et al., 2020b).

1814 High salinity waters from the western Arabian Sea and the western Equatorial Indian Ocean can route to the Bay of Bengal  
 1815 via the Somali Current and the Indian Ocean EUC (Sanchez-Franks et al., 2019). Changes in strength of the Bay of Bengal  
 1816 high salinity core are linked to the convergence of the East Africa Coastal Current and the wintertime southward-flowing  
 1817 Somali Current, with anomalously strong equatorial Undercurrent (Fig. 19). Because of the seasonal reversal of currents,  
 1818 two junctions form naturally, one in the western equatorial Indian Ocean (Somali Current) and another south of India  
 1819 (monsoon currents), which effectively act as ‘railroad switches’ rerouting water masses to different basins in the Indian  
 1820 Ocean depending on the season (Fig. 19, Sanchez-Franks et al., 2019).

1821

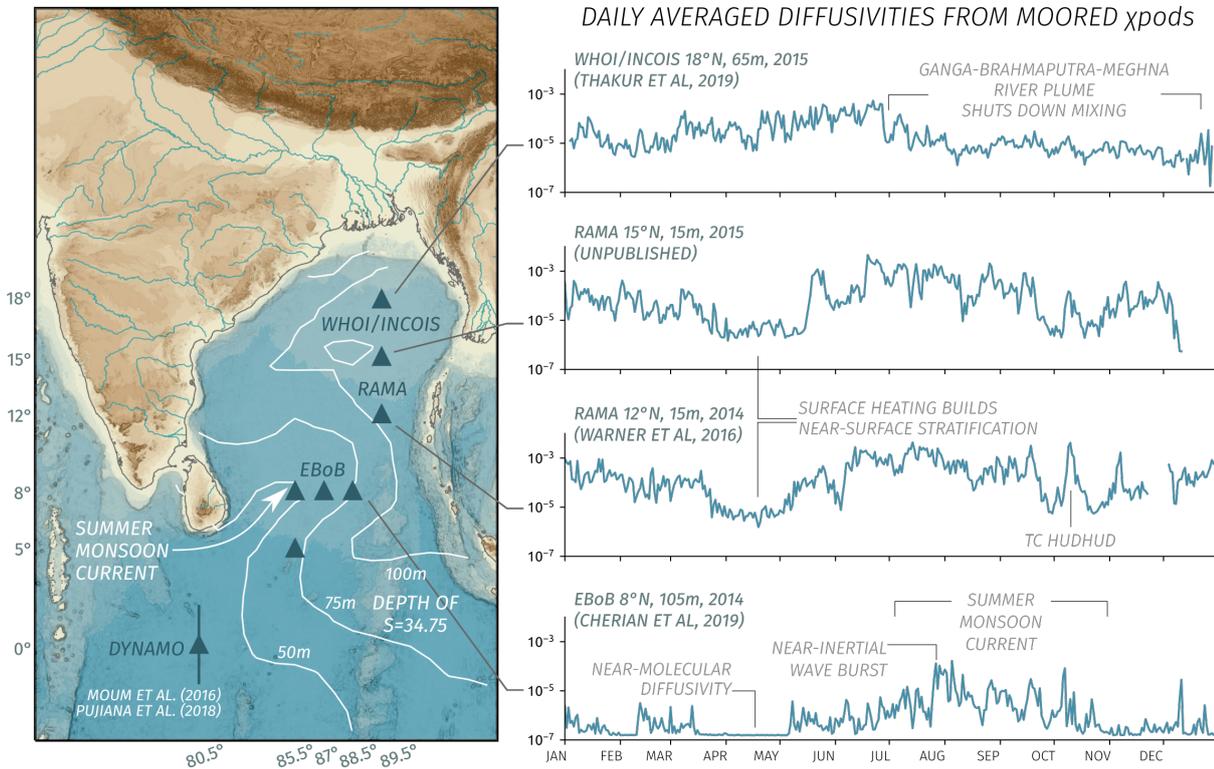

1822 **Figure 19: Seasonal circulation pathways in the northern Indian Ocean, or Railroad Switch schematic, on subsurface**

### 1828 7.3 Vertical Mixing

1829 Strong stratification in the Bay of Bengal plays a critical role in setting the upper ocean turbulence, notably leading to  
1830 relatively weak mixing compared to other regions (e.g. Gregg et al., 2006). However, large-scale inferences suggest that  
1831 mixing must play a key role in at least two regards. First, the net surface flux during the southwest monsoon on average is  
1832 warming but yet the SST cools (Shenoi et al, 2002). Second, the large scale salt balance must be closed through upward  
1833 mixing of high-salinity water carried into the Bay via the Summer Monsoon Current (Vinayachandran et al., 2013).

1834 Recent year-long direct measurements of mixing in the Bay have helped link the seasonal cycle in mixing to the seasonal  
1835 cycle of winds, currents and freshwater. These year-long measurements were recorded by mixing meters called  $\chi$  pods.  $\chi$  pods  
1836 consist of two temperature microstructure sensors and a suite of ancillary sensors necessary to infer the rate of dissipation  
1837 of temperature variance at 1Hz frequency for up to a year (Moum & Nash, 2009).  $\chi$  pods have been deployed on moorings  
1838 in three different regions of the Bay (Figure 20): the air-sea buoy at 18°N, top 65m (Thakur et al., 2019), RAMA moorings  
1839 along 90°E (mixing measurements at 15m, 30m and 45m; Warner et al. 2016), and the EBoB array in the south-central Bay  
1840 (mixing measurements spanning between 30m and 100m at sites in the region 85°E-88°E, 5°N-8°N, Cherian et al., 2020).  
1841 Across the basin, turbulence within and near the base of the mixed layer shows strong seasonality that parallels the monsoon  
1842 cycle in winds (Thakur et al., 2019, Warner et al., 2016). In the thermocline of the south-central Bay (EBoB array), mixing  
1843 is correlated with packets of downward propagating near-inertial waves implicating wind forcing. As depicted in Figure 20,  
1844 both near-surface and thermocline mixing are relatively high during the NE and SW monsoons (Dec-Feb, May-Sep) and  
1845 relatively low during the transition (Mar, Apr). Cyclones during the post-monsoon months of October and November can  
1846 drive a hundredfold increase in near-surface mixing both locally and throughout the Bay (Warner et al. 2016). Mixing  
1847 profiles collected by a fast thermistor on a CTD rosette during a basin-wide survey before and after the passage of cyclone  
1848 Madi (6-12 Dec, 2013) show a basin-wide increase in diffusivity linked to near-inertial waves forced by the cyclone  
1849 (Wijesekera et al., 2016b).

1850

1851 **Figure 20: Annual cycle of daily averaged temperature diffusivities derived from  $\chi$ pod measurements. The data are**  
 1852 **from two different years, 2014 and 2015, depending on location. Note the similar wind-forced seasonal cycle at 12°N,**  
 1853 **15m and 15°N, 15m and the dramatically different seasonal cycle at 8°N, 105m (reflecting near-inertial wave activity)**  
 1854 **and at 18°N, 65m reflecting freshwater influence.**

1855 The influence of freshwater is a critical caveat to the above generalizations: the arrival in August of the Ganga-Brahmaputra-  
 1856 Meghna freshwater plume at 18°N has been observed to suppress turbulence (diffusivity  $K_T < 10^{-5} \text{ m}^2 \text{ s}^{-1}$ ) for multiple  
 1857 months (Aug-Nov) at depths of approximately 50-65 m (Figure 20). This buoyant lens limited the vertical extent of the  
 1858 influence of Tropical Cyclone Komen as compared to a previous (weaker) storm (Chaudhuri et al 2019, Thakur et al 2019).  
 1859 Similar observations of extremely weak turbulence below strong, salinity-stratified surface layers have been reported  
 1860 throughout the Bay using data from a variety of platforms: ship-based microstructure (Jinadasa et al, 2016) profiling floats  
 1861 with a temperature microstructure sensor (Shroyer et al, 2016) and glider-based microstructure measurements (St. Laurent  
 1862 and Merrifield, 2017). Lucas et al (2016) find that near-inertial shear was elevated at the base of the mixed layer but not  
 1863 elevated at the base of the barrier layer — direct evidence that salinity stratification can insulate deeper depths from the  
 1864 effects of near-surface forcing (downward propagating near-inertial waves in this case). Li et al. (2017) use a combination  
 1865 of observations and modelling results to demonstrate that barrier layers in the Bay of Bengal influence the amplitude of

1866 intraseasonal oscillations in SST and precipitation. However, a recent coarse resolution coupled modelling study suggests  
1867 that freshwater has little influence on SST or rainfall, since the SST tendency caused by a reduction in mixing is offset by  
1868 changes in surface heat fluxes (Krishnamohan et al., 2019)

1869 Surface freshwater advection can create subsurface reservoirs of heat and salt that can be accessed when the winds are strong  
1870 enough, such as during cyclones that regularly form in the Bay during October and November. In one dramatic example  
1871 Qiu et al (2019) report up to 5 psu increases in SSS and only a smaller 0.5°C decrease in SST following the passage of  
1872 Cyclone Phailin (2013). In this case, mooring records indicate that mixing was limited to the isothermal layer (Chaudhuri  
1873 et al. 2019). Subsurface warm layers (i.e. temperature inversions stabilized by strong salinity stratification) are also observed,  
1874 representing a reservoir of heat that can be accessed if a storm excites enough turbulence, as appears to have happened  
1875 during the passage of Cyclone Hudhud (Warner et al, 2016). The influence of stratification in limiting the extent of vertical  
1876 mixing and creating subsurface warm layers mean that cyclone-induced cooling is generally either weak or negligible in the  
1877 Bay, unlike in other ocean basins (Sengupta et al, 2008).

1878 Long periods of near-molecular diffusivities (weeks to a month) were also inferred at multiple  $\chi$  pods along 8°N between 50  
1879 m and 100 m during transition months of March and April. Here freshwater insulation does not appear to be the major factor.  
1880 Instead the period of weak turbulence may be linked to low levels of near-inertial energy (a consequence of weak wind  
1881 forcing in March and April) and the absence of strong mean oceanic flows during these transition months (Cherian et al  
1882 2020). Relatively weak diffusivities are also present in the LADCP fine structure estimate of depth-integrated (thermocline  
1883 to bottom) turbulent kinetic energy dissipation  $\varepsilon$  (Kunze et al, 2006) and the Argo fine structure-based 250-500 m diffusivity  
1884 estimates of Whalen et al. (2012). The extended presence of such weak turbulence suggests that the Bay's internal wave  
1885 field is weaker than might be expected from the Garrett-Munk internal wave spectrum at least during some months of the  
1886 year. Another (related) question is the issue of representation of such weak background mixing in climate models and  
1887 whether that matters to known biases in such models.

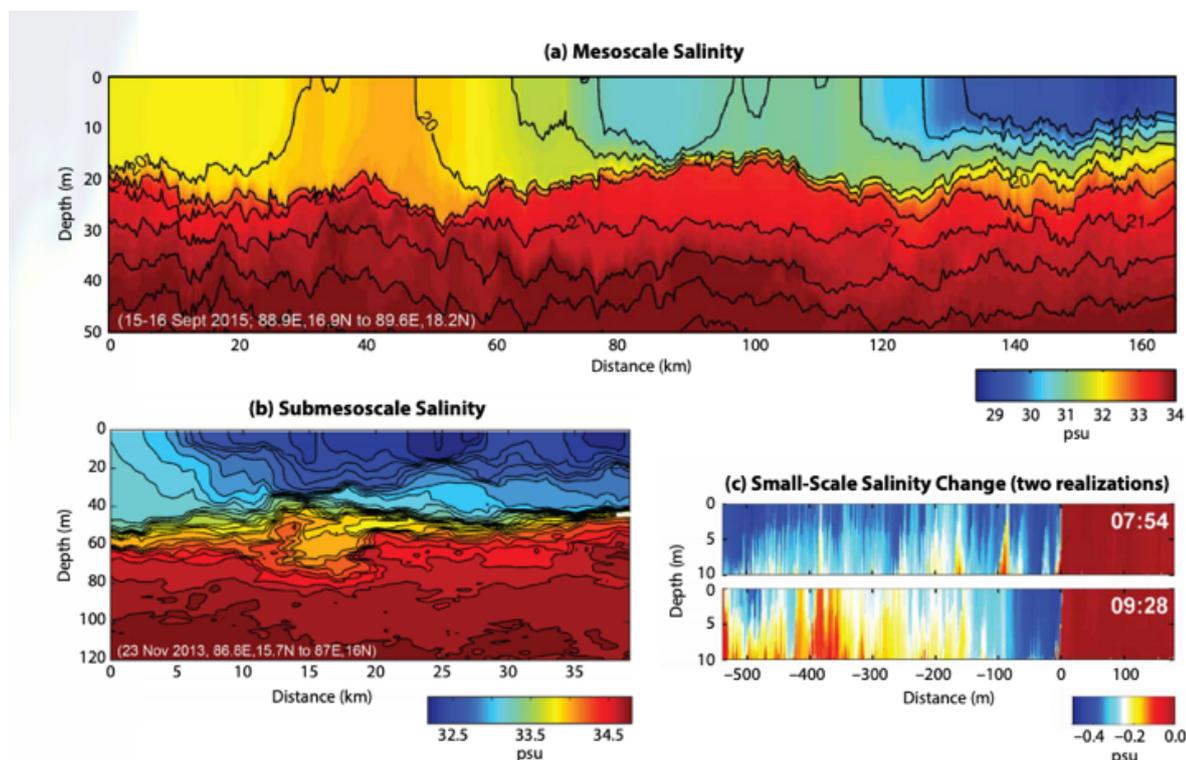

1888 Published efforts so far have been directed towards understanding the modulation of turbulence by larger-scale variations  
1889 in the wind, currents and freshwater. Questions remain as to the impact of small-scale mixing on the large-scale long-term  
1890 T-S structure in the Bay as well as the influence of subsurface mixing and the ensuing modification of SST on coupled  
1891 ocean-atmosphere phenomena such as the MJO and the MISO (Section 3.2)

#### 1892 **7.4 Where vertical and lateral processes meet: The Role of Submesoscale**

1893 Freshwater inflow from the Ganga-Brahmaputra-Meghna (GBM) and the Irrawady river in the Bay of Bengal is stirred by  
1894 the mesoscale eddies into sharp frontal gradients (in salinity and in density) at O(1-10km) scales with shallow vertical extent.  
1895 These fronts are acted upon by winds seasonally, setting up complex sub-mesoscale structures with salinity differences O(1

1896 psu) over 1-10 km, developing bore-like features with  $O(0.5 \text{ psu})$  difference over a few meters horizontally (Nash et al 2016;  
1897 Figure 21). Wavenumber spectra of temperature at  $O(1\text{-}10\text{km})$  scale show a  $-2$  slope in many regions of the Bay (Mackinnon  
1898 et al 2016), a signature of frontogenesis in the Bay at these scales. The BoB is thus replete with fronts which evidently slump  
1899 at sub-mesoscales due to both symmetric and baroclinic instabilities (Ramachandran et al. 2018), and show higher  
1900 stratification near fronts (Sree Lekha 2019) .

1901

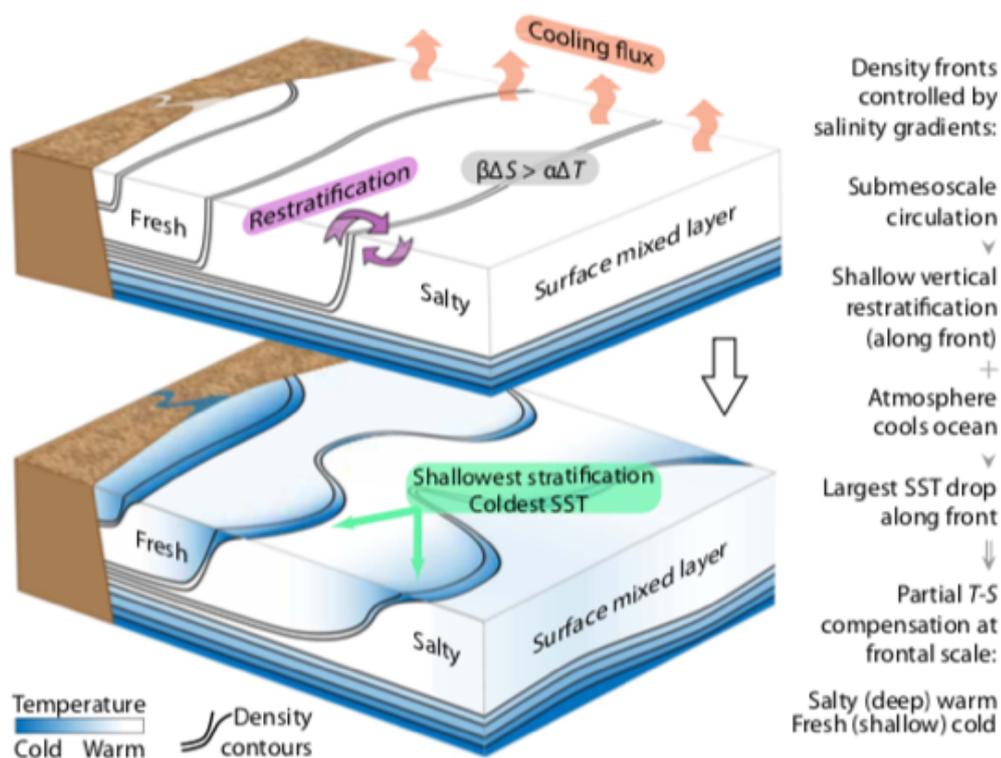

1902 **Figure 21: Observed salinity gradients at mesoscale, sub-mesoscales and small horizontal scales from in the Bay of**  
1903 **Bengal (Nash et al. 2016).**

1904 The fronts and filaments at  $O(1\text{-}10\text{km})$ , which are dominated by salinity gradients and weakly compensated, have strong  
1905 implications for setting up the density stratification in the top 50-100m in the BoB (Section 4.4.1). The stratification in this  
1906 depth range often has multi-layered structure with stratification varying at  $O(1\text{-}10\text{km})$  scales (Lucas et al 2016), showing  
1907 evidence that the stratification in the Bay cannot be explained simply in terms of vertical processes, and horizontal  
1908 submesoscale processes are intimately coupled with the vertical processes at these scales. Ramachandran et al. (2018) show  
1909 that a mesoscale strained region with strong fronts ( $O(1\text{kg}/\text{m}^3)$  over 40km) and weak down front wind shows multiple  
1910 dynamical signatures of sub-mesoscale instabilities. Ageostrophic secondary circulations arising near the fronts and the  
1911 accompanied sheared advection plays an important role in setting the stratification (Pham and Sarkar 2019). Both

1912 observations and process modeling show  $O(1-10\text{km})$  patches of low potential vorticity consisting of subducted warm water  
1913 patches due to combination of baroclinic and forced symmetric instabilities, creating barrier layers whose thickness varies  
1914 laterally at sub-mesoscales (Ramachandran and Tandon, 2020 JGR-in review).

1915 During winter, the temperature gradients in the horizontal compensate for the salinity gradients to reduce the density  
1916 gradient, and the sub-mesoscale processes in BoB lead to a unique situation. Jaeger & Mahadevan (2018) show that surface  
1917 cooling fluxes combined with submesoscale instabilities of the haline fronts during wintertime leads to shallower mixed  
1918 layers on the less saline (cooler) side. Therefore, cold SSTs in wintertime in the Bay mark surface trapped waters (Fig. 22),  
1919 whereas in other regions of the world ocean, cold filaments mark upwelling of nutrient-rich waters. Further, since the shallow  
1920 fresher mixed layers lead to larger drops in temperature, this develops the correlation between SST and SSS at  $O(1-10\text{km})$   
1921 scales.

1922

1923 **Figure 22: Interaction of submesoscale salinity gradients with atmospheric cooling leads to shallow cold regions**  
1924 **(From Spiro Jaeger and Mahadevan, Science Advances 2018)**

## 1925 **7.5 Putting the Pieces Together**

### 1926 **7.5.1 Coupled ocean-atmosphere phenomena**

1927 Due to the presence of a barrier layer over much of the Bay of Bengal, entrainment and upwelling of waters from the  
1928 thermocline are inhibited, and the evolution of SST is largely driven by net air-sea heat flux variability (Duncan and Han,  
1929 2009). However, the dependency of SST on surface fluxes is controlled by subsurface processes such as formation of barrier  
1930 layers, entrainment warming and cooling of the mixed layer, penetrative solar radiation and zonal advection (Thangaprakash  
1931 et al., 2016). Advection is important in influencing the SST as lateral variations in the mixed layer depth alone can result in  
1932 variations in air-sea fluxes of roughly  $20 \text{ Wm}^{-2}$  over distances of kilometers (Adams et al., 2019). This magnitude is similar  
1933 to uncertainty in air-sea flux products (Weller et al. 2016) thus implying that variations in sub-mesoscales are important for  
1934 heat balance in the northern BoB. The coupling of the ocean-atmosphere over BoB at large scales implicates the air-sea  
1935 interaction and the mixed layer heat budget in BoB (Rahaman et al. 2019), although at oceanic mesoscale and finer scales  
1936 in the horizontal and at sub-seasonal timescales this coupling is a topic of active research.

### 1937 **7.5.2 Implications for biogeochemistry in the Bay**

1938 Eddies in the central BoB arise not by the baroclinic instability of boundary currents but rather due to planetary wave  
1939 dynamics off the equator that triggers coastal Kelvin waves around the Bay. The Kelvin waves then trigger south-westward  
1940 propagating Rossby waves, which result in large mesoscale structures in the Bay (Cheng et al. 2018). The Andaman and  
1941 Nicobar Islands are also shown to be very important for the generation of these eddies; without these islands the number of  
1942 eddies would have reduced to almost half in the western bay of Bengal (Mukherjee et al., 2019). These eddies provide much  
1943 of the horizontal stretching and stirring of the tracers, including those relevant to the ecosystems

1944 Eddies have tremendous potential to influence ocean biogeochemistry by providing “new” nutrients to the ocean’s euphotic  
1945 layer (Stramma et al., 2013). However, we do not fully understand the spatial distribution of nutrients within the eddy  
1946 surface area – e.g., there is a debate whether nutrients upwell at the core and downwell at the edge of the eddy, or vice versa.  
1947 Further, such discrepancy also continues in the type of eddies – i.e., whether upwelling occurs in cyclonic and downwelling  
1948 occurs in anticyclonic eddies and vice versa (Mahadevan, 2014; Mahadevan et al., 2012; Martin and Richards, 2001). But  
1949 there is a consensus that eddies do impact biogeochemistry (McGillicuddy et al., 2007).

1950 There have been only a handful of studies on the role of eddies in biological productivity in this region (Kumar et al., 2007;  
1951 Singh et al., 2015). Kumar et al. (2007) observed an increase in surface nutrients in the Bay through eddies during both fall-  
1952 2002 and spring-2003 followed by higher biomass. Despite being highly eutrophic, biological activity did not increase  
1953 following cyclonic eddies during the summer-2003 in the northern Bay (Muraleedharan et al., 2007). But primary production  
1954 switched from ‘regenerated’ to ‘new’ production during summer-2003. In a  $^{15}\text{N}$  based new production estimate to assess the

1955 role of cyclonic eddies in enhancing primary production, Singh et al. (2015) carried out measurements of  $^{13}\text{C}$  based primary  
1956 production at four stations in the Bay of Bengal (around a cyclonic eddy close to  $17.8^\circ\text{N}$ ,  $87.5^\circ\text{E}$ ) during winter 2007. The  
1957 measurements sampled one cyclonic eddy during the campaign. The highest surface productivity ( $2.71 \mu\text{M C d}^{-1}$ ) and  
1958 chlorophyll a ( $0.18 \mu\text{g L}^{-1}$ ) were observed within the eddy due to intrusion of nutrients from subsurface waters. Given new  
1959 nitrogen input via vertical mixing, river discharge or aerosol deposition, the additional primary production due to this new  
1960 nutrient input and its contribution to the total production increased from 40% to 70%. Eddies could be a reason for the  
1961 otherwise unexplained high new production rates in the Bay of Bengal (Singh and Ramesh, 2015). Eddies also seem to have  
1962 a potential for transferring a high fraction of fixed carbon to the deep.

## 1963 8. Summary and open questions

1964 This paper illustrates that IIOE-2 and related efforts have driven a suite of new studies in the Indian ocean. An increase in  
1965 high quality observations (both increased spatial resolution and the acquisition of longer time series) has led to a substantial  
1966 increase in our understanding of processes and interactions. These in-situ observations, in combination with remote sensing,  
1967 detailed syntheses and modeling have increased our knowledge of the surface circulation and its complex implications for  
1968 biological production, along with an increased understanding of air-sea interaction in the Indian ocean.

1969 There are, however, a number of outstanding questions that require prioritised efforts. Compared to the Atlantic and Pacific,  
1970 where the important boundary currents are now being monitored with a suite of gliders with repeated and sustained sections,  
1971 the boundary currents and their variability in the Indian Ocean remain poorly constrained. Given the anomalous warming  
1972 of the Indian Ocean, the frequency of heatwaves, and the population supported by the Indian Ocean and Monsoons, the air-  
1973 sea fluxes and the coupled atmosphere-ocean exchange in this ocean remain poorly understood at many scales.  
1974 Understanding of the intermediate, deep and abyssal layer circulation and the vertical overturning cells that connect these  
1975 layers in the Indian Ocean is lacking.

1976 There are still large uncertainties in air-sea fluxes. Even in the regional basin of the Bay of Bengal where there have been  
1977 focused international efforts, the river discharge and rain need to be better represented in the models, along with the  
1978 processes that set the shallow salinity stratification. These have important feedbacks on the SST which impacts atmospheric  
1979 convection with a global reach. At longer time scales, the salinity feedbacks to climate at interannual to decadal timescales  
1980 need to be investigated in further detail. The decadal variability of the Indian Ocean Dipole and its link to the Pacific decadal  
1981 variability also needs to be better understood.

1982 On the influence of small scale mixing, increased measurements of ocean mixing both along the equator and new long term  
1983 measurements in the Bay of Bengal, have shown intensively enhanced mixing during the passage of eddies and during

1984 cyclones. However, there are still significant uncertainties in subsurface ocean mixing in setting the large scale balance in  
1985 the Indian ocean.

1986 There are still many gaps in current understanding of Indian Ocean biogeochemical cycles. Although the characterization  
1987 of the temporal and spatial variability in chlorophyll concentration and primary production has greatly improved as a result  
1988 of recent in situ measurements and satellite remote sensing, there are still many areas where there is little or no information  
1989 about how this relates to changes in planktonic food web structure and particulate organic matter export to the deep ocean.  
1990 Although nutrient limitation patterns were not discussed in this review, it should be pointed out that the importance of  
1991 nitrogen versus iron and silica limitation in the Arabian Sea and elsewhere in the Indian Ocean is still a subject of debate -  
1992 more nutrient and trace metal measurements are needed along with nutrient limitation bioassays throughout the Indian  
1993 Ocean.

1994 The number of nitrogen fixation rate measurements in the Indian Ocean has also increased significantly over the last decade,  
1995 but the importance of this process as a source of new nitrogen to the surface ocean has been quantified in only a few regions  
1996 (e.g., off northwest Australia) and its contribution to bloom formation (e.g., the Madagascar Bloom) is still uncertain. From  
1997 a spatial standpoint, the quantification of biogeochemical variability in the northern Indian Ocean (Arabian Sea and Bay of  
1998 Bengal) has benefited, in particular, from numerous shipboard measurements, moorings and biogeochemical Argo float  
1999 deployments in the last decade. Many questions still remain, for example, related to the influence of freshwater inputs on  
2000 biogeochemical cycles in the Bay of Bengal. Remarkably, the biogeochemical and ecological impacts of the Indonesian  
2001 Throughflow have been examined in only a handful of studies. Similarly, there are very few studies that focus on the  
2002 biogeochemical and ecological impacts of the Seychelles-Chagos Thermocline Ridge (SCTR). The ITF and the SCTR are  
2003 unique features of the Indian Ocean, yet the understanding of their biogeochemical and ecological impacts is rudimentary  
2004 at best. Finally, the quantification of biogeochemical variability in the Leeuwin and Agulhas Currents and adjacent waters  
2005 has also benefited from recent measurements, though it is important to point out that the biogeochemical impacts of boundary  
2006 currents in the Indian Ocean are still poorly understood compared to the Atlantic and Pacific.

2007 Modeling and observational efforts have both pointed to the increased role of air-sea coupling at higher frequencies to  
2008 improve the predictions of sub-seasonal Monsoon forecasts. Observations and models indicate that MISOs may be slowing  
2009 down because of the warming in the Indian Ocean (e.g. Sabeerali et al. 2013), which needs to be understood better for  
2010 providing reliable monsoon predictions and projections in this climate vulnerable region.

#### 2011 **Code Availability**

2012 No original data analyses were undertaken as part of this review paper.

2013 **Data Availability**

2014 No original data analyses were undertaken as part of this review paper. All data presented in this manuscript have been  
2015 previously published and are available from sources identified in the original manuscripts.

2016 **Author Contributions**

2017 HEP and AT designed the review, wrote the introductory and concluding parts and sections in their areas of expertise. HP  
2018 and AT reviewed the contributions of the authors and made editorial adjustments. RF wrote sections in his area of expertise  
2019 and contributed editorial advice. RH wrote the sections on biogeochemical variability in Section 4. All co-authors  
2020 contributed to the writing of sections relevant to their areas of expertise. All authors contributed to refining the manuscript  
2021 for submission.

2022 **Competing interests**

2023 The authors declare that they have no conflict of interest.

2024 **Acknowledgements**

2025 The authors acknowledge the sustained efforts of researchers and funding agencies in observing and modelling the oceanic  
2026 and atmospheric processes that control climate variability in the Indian Ocean region. These contributions during the  
2027 International Indian Ocean Expeditions (I and II) and in the intervening years are fundamental to improving our knowledge  
2028 of these systems and increasing our skill at forecasting variability and extreme events. We thank the IIOE-2 leadership team  
2029 (<https://iioe-2.incois.gov.in/>) for their unwavering efforts to share new discoveries and promote understanding of the  
2030 importance of the Indian Ocean to the climate system and Earth's inhabitants. HEP acknowledges support from the  
2031 Australian Government's National Environmental Science Programme.
