Short summary

15 The summer South Vietnam Upwelling develops in the South China Sea, under the influence of monsoon winds. Cold, nutrient-rich waters rise to the surface, where photosynthesis occurs. This biologically active area is essential for the fishing activity. We have developed a very high resolution model to better understand the factors that drive the variability of this upwelling, along the coast and offshore: summer mean to daily chronology of wind, mesoscale ocean dynamics to coastal circulation.

20

Abstract.

The South Vietnam Upwelling (SVU) develops in the South China Sea off the Vietnamese coast under the influence of southwest monsoon winds. A very high resolution configuration (1 km at the coast) of the SYMPHONIE model was developed over the western coastal region of the South China Sea. A simulation was performed over the period 2009-

25 2018 to study the functioning, variability and influence of oceanic circulation and hydrology in the coastal region, in particular of the SVU. The realism of the simulation in terms of representation of ocean dynamics and water masses, from daily to interannual and coastal to regional scales, is assessed here in detail by comparison with available satellite data and 4 sets of in-situ observations. The interannual variability of the SVU is examined for its 4 main development areas: the southern (SCU) and northern (NCU) coasts, the offshore area (OFU), and the Sunda Shelf area off the Mekong Delta

30 (MKU). For the SCU and OFU, our results confirm the driving role of the summer mean wind and the summer circulation over the offshore area in the interannual variability of the upwelling intensity. They moreover reveal the impact of the spatial and temporal organization of mesoscale ocean structures and high frequency atmospheric forcing. For the NCU, the upwelling interannual variability does not seem to be related to regional scale forcing and dynamics, but is mainly determined by coastal mesoscale structures and circulation : similar summer wind conditions can be associated with very

35 contrasting NCU intensities, and vice versa, depending on the circulation in the NCU area. Finally, our study reveals that upwelling also develops off the Mekong Delta, with an interannual variability mostly determined by the summer wind and the wind-driven circulation over the SVU region.

1. Introduction

40   Ocean circulation in the South China Sea (SCS), one of the largest semi-enclosed seas in the world (Figure 1), is under the influence of several factors of variability at different scales (typhoons, seasonal monsoon, interannual to decadal variability, climate change, Wyrtki 1961, Herrmann et al. 2020, 2021). SCS is moreover impacted by human activities, with highly densely populated coastal areas (CIESIN 2018), which generate problems such as marine pollution (release of industrial, agricultural or domestic contaminants, such as pharmaceuticals, pesticides, heavy metals, plastics …).

45   Reciprocally, coastal societies are highly dependent on marine resources (fisheries and aquaculture, tourism…). SCS also contributes to the functioning and variability of regional climate through air-sea coupling (Xie et al. 2003,2007, Zheng et al. 2016) but also of global climate through its role in the transformation of surface water masses of the global ocean circulation (South China Sea Throughflow, Fang et al. 2009, Qu et al. 2009). It is therefore essential to better understand and model the full range of SCS ocean dynamics at different scales which intervene in the transport and fate of water

50   masses, in the water and energy cycle, in the functioning of planktonic ecosystem (via their impact on the transport and mixing of nutrients and organic matter, Ulses et al. 2016, Herrmann et al. 2017), and in the propagation of contaminants at sea.

      The large-scale summer circulation over the SCS is usually characterized by an overall anticyclonic circulation resulting

55   from southwest summer monsoon winds (Wang et al. 2004). It is composed more precisely of a western boundary current and a dipole structure that develops along the Vietnamese coast, with an anticyclonic gyre (AC) in the south and cyclonic gyre (C) in the north. This dipole structure induces northward/southward alongshore coastal currents which are the western components of the AC/C gyres, and a marked eastward offshore jet that develops in the area of convergence of both coastal currents and between both gyres, around ~12°N (Xu et al. 1982, Fang et al. 2002, Xie et al. 2003,2007, Chen

60   and Wang 2014, Li et al. 2014, 2017).

      Summer wind forcing and this resulting large-scale circulation induce the South Vietnam Upwelling (SVU), one of the main components of the SCS summer ocean dynamics. The SVU strongly influence halieutic resources through its impact on bio-productivity (Bombar et al. 2010, Loick et al. 2007, Loisel et al. 2017, Lu et al. 2018) and affects regional climate

65   (Xie et al. 2003, Zheng et al. 2016). It is driven at the first order by atmospheric forcing, namely Ekman transport and pumping induced by the southwest monsoon wind (Xie et al. 2003). It is moreover reinforced by the eastward jet that enhances the offshore advection of coastal water (Dippner et al. 2007) and by the combination of wind-induced Ekman pumping and positive surface current vorticity associated with cyclonic eddies in the offshore area (Da et al. 2019, Ngo et al. 2021).

70

      Previous field campaigns (Dippner et al. 2007, Bombar et al. 2010, Loick-Wilde et al. 2017), satellite observations (Xie et al. 2003, Kuo et al. 2004, Ngo and Hsin 2021) and modeling studies (Li et al. 2014, Da et al. 2019), showed that the SVU can strongly vary from one year to another. This interannual variability depends in particular on the intensity of the summer monsoon southwest wind and on ENSO, but also on cross-equatorial winds (Wu et al. 2019) and decadal climate

75   variability (Wang et al. 2020). Two recent studies used long simulations or datasets to establish statistical relationships between the interannual variability of SVU intensity, the atmospheric forcing and the background circulation. Da et al. (2019), using a 1/12° (9 km) 14-years simulation, and Ngo and Hsin (2021), based on ¼° (28 km) datasets of 38-years SST and reanalysis winds and 28-years satellite-altimeter derived sea surface current, showed that the upwelling develops both along and offshore the Vietnamese coast. They quantified the link between the interannual variability of the southern

80   coastal and offshore upwellings and the intensity of the summer ocean circulation (eastward jet, AC/C dipole and associated northward/southward boundary currents) induced by the summer monsoon wind. These studies moreover showed that upwelling sometimes develops along the northern part of the coast from 11°N to 15°N. Da et al. (2019) also revealed and quantified the important contribution of ocean intrinsic variability (OIV) in the SVU interannual variability in the offshore area, mainly related to the role of vorticity associated with mesoscale structures of strongly chaotic nature.

85   Chen et al. (2012) moreover showed that tides and river plumes could be additional mechanisms involved in SVU dynamics.

Most of previous studies were based on numerical or observational datasets associated with several methodological choices and hypothesis : short study periods and limited spatial coverage of in-situ datasets, models resolution not finer

90   than ~10 km, cloud cover and proximity of the coast hindering satellite data quality, gridded current datasets built from along-track sea level satellite data that can not capture small scale and non-geostrophic dynamics, synoptic view based on spatially and seasonally integrated indicators, no or simplified representation of tides and river plumes… This limited their ability to capture or represent the full range of scales involved in the SVU variability, which goes from regional circulation to submesoscale and coastal dynamics and from daily to interannual variability. Further investigations are

95   therefore needed to better understand the role of these processes at different scales and their interactions, in order to improve our knowledge of ocean dynamics and its impacts in the SCS and VNU regions. Numerical modeling is a valuable tool for that.

The objective of the work presented here is therefore both methodological and scientific. With the goal of better modeling

100   and understanding the functioning, variability and influence of ocean dynamics in this area, we developed a very high resolution configuration of a numerical ocean model, able to represent ocean dynamics and water masses at all scales from the Vietnamese coast to the offshore region. This numerical tool is presented in Part 2, and its ability to represent ocean dynamics and water masses is evaluated in Part 3. We then used this tool to examine the variability of the SVU at different scales. Here we first focus on its interannual variability over its 4 main areas of development, examining in

105   particular the role of high frequency and small scale dynamics. This analysis is presented in Part 4. Results are summarized in Part 5.

2.   Methodology : numerical tool and observation datasets

2.1.   The regional ocean hydrodynamical model SYMPHONIE

110   The 3-D ocean circulation model SYMPHONIE (Marsaleix et al. 2008, 2019) is based on the Navier-Stokes primitive equations solved on an Arakawa curvilinear C-grid under the hydrostatic and Boussinesq approximations. The model makes use of an energy conserving finite difference method described by Marsaleix et al. (2008), a forward-backward time stepping scheme, a Jacobian pressure gradient scheme (Marsaleix et al. 2009), the equation of state of Jackett et al. (2006), and the K-epsilon turbulence scheme with the implementation described in Michaud et al. (2012) and Costa et al.

115   (2017). Horizontal advection and diffusion of tracers are computed using the QUICKEST scheme (Leonard 1979) and vertical advection using a centered scheme. Horizontal advection and diffusion of momentum are each computed with a fourth order centered biharmonic scheme as in Damien et al. (2017). The biharmonic viscosity of momentum is calculated according to a Smagorinsky-like formulation derived from Griffies and Hallberg (2000). The lateral open boundary

conditions, based on radiation conditions combined with nudging conditions, are described in Marsaleix et al. (2006) and

120   Toublanc et al. (2018). The VQS (vanishing quasi-sigma) vertical coordinate described in Estournel et al. (2021) is used to avoid an excess of vertical levels in very shallow areas while maintaining an accurate description of the bathymetry and reducing the truncation errors associated with the sigma coordinate (Siddorn et al. 2013).

The configuration used in this study is based on a standard horizontal polar grid (Estournel et al. 2012) with a resolution

125   decreasing linearly seaward, from 1 km at the Vietnamese coast to 4.5 km offshore (Figure 1), and 50 vertical levels. This configuration zoomed on the Viet Nam coast is hereafter referred to as the VNC configuration. The simulation runs from January 1st, 2009 to December 31st, 2018. The atmospheric forcing is computed from the bulk formulae of Large and Yeager (2004) using the 3-hourly output of the European Center for Medium-Range Weather Forecasts (ECMWF) 1/8° atmospheric analysis, distributed on http://www.ecmwf.int. Initial ocean conditions and lateral ocean boundary conditions

130   are prescribed from the daily outputs of the global ocean 1/12° analysis distributed by the Copernicus Marine and Environment Monitoring Service (CMEMS) on http://marine.copernicus.eu. The implementation of tides follows Pairaud et al. (2008, 2010). It includes tidal amplitude and phase introduced at open lateral boundaries and the astronomical plus loading and self-attraction potentials, and considers the 9 main tidal harmonics, provided by the 2014 release of the FES global tidal model (Lyard et al. 2006). As the absence of tides in the 3D COPERNICUS simulation led to an

135   underestimation of T and S mixing near the bottom, we add to the COPERNICUS fields the effect of the tidal mixing effect, using the parameterization described in Nguyen-Duy et al. (2021). The boundary conditions for rivers are described in Reffray et al. (2004) and Nguyen-Duy et al. (2021). 3 kinds of river runoff data were available over the region : monthly climatology data for 17 rivers, yearly climatology data for 1 river, and daily real-time data for 18 rivers (see Figure 1 for locations of river mouths). The total freshwater discharge of the 36 rivers is equal on average over 2009-2018 to 21.4.

140   10^3 m^{3}s^{-1}. To account for the interannual variability of river discharges for climatological data, we applied to those climatological data a yearly multiplying coefficient obtained from daily data time series.

2.2.   Observation data

2.2.1.   Satellite data

Available satellite observations are used to evaluate the ability of our model to reproduce sea surface characteristics over

145   the study area. For model-data comparisons, model outputs are interpolated on spatial and temporal grids of satellite data:

●   OSTIA (Operational Sea Surface Temperature and Sea Ice Analysis) level 4 analysis daily SST produced using an optimal interpolation approach by the Group for High Resolution SST (GHRSST, UK MetOffice, 2005) on a global 0.05° grid over the period 2009-present, available at ftp://data.nodc.noaa.gov/pub/data.nodc/ghrsst/L4/GLOB/UKMO/OSTIA/.

150   ●   Boutin et al. (2018) version 3 of 9-day-averaged level 3 SSS produced from SMOS microwave imaging radiometer with aperture synthesis (MIRAS) at a 0.25° resolution over 2010-2017, available at ftp://ext-catds-cecos-locean:catds2010@ftp.ifremer.fr.

155   ●   Daily altimetry sea level (SSH) data produced by AVISO (Archiving, Validation and Interpretation of Satellite Oceanographic data) at a 0.25° resolution over the period from 1993 up to now (Ablain et al. 2015, Ray and Zaron 2015), distributed by the CMEMS on http://marine.copernicus.eu. For both simulated and observed time series, the daily

altimetry sea level anomaly (SLA) is obtained by removing at each point the SSH temporal average over 2009-2018 :

$$SLA(x,y,t) = SSH(x,y,t) - \underline{SSH(x,y,t)}$$

160   **2.2.2.   In-situ data**

To evaluate the ability of the model to reproduce hydrological characteristics of water masses, we collected and processed temperature and salinity in-situ data available over the study area (see measurements characteristics in Table 1 and locations in Figure 2). For comparison purposes, modeled outputs are spatially and temporally co-localized with observational data:

165

*   ARGO floats : over the period 2009-2018 more than 3 600 profiles were collected in our study area, available on ftp://ftp.ifremer.fr/ifremer/argo/geo/pacific_ocean/

*   Sea-glider Vietnam – US campaign : under the framework of a cooperative international research program, including
170   Vietnamese and U.S. scientific institutions (Rogowski et al. 2019), a glider-based observational program was initiated. Seaglider sg206 was deployed on 22 Jan 2017 and crossed the southward currents near the shelf break approximately 4 times before the steering mechanism malfunctioned on 21 Apr 2017. Ultimately, the mission ended on 16 May 2017 without recovery. The glider collected 552 vertical profiles over the 114 days of deployment (hereafter called GLIDER data).

175

*   ALIS R/V data : the VITEL cruise was organized in May – July 2014 on the French scientific vessel ALIS (P.I S. Ouillon, funding CNES/TOSCA). During the trajectory of the ALIS vessel in the SCS, surface temperature and salinity were measured every 6 seconds, from 10 May 2014 to 28 July 2014 by the automatic thermosalinometer Seabird SBE21 (hereafter called ALIS-TSG data).

180

*   IO-18 data : Meteorological, current, temperature, and salinity parameters were measured in the framework of the Vietnamese State project (code DTDL.CN-28/17, PI. Vo Si Tuan) in September 2018. Measurements were performed by a Sea-Bird 19plus CTD at 19 stations, including 16 instantaneous measurement stations and 3 stations where measurements were collected every 3 hours during 24 hours, producing 43 T,S profiles.

185

2.3.   Definition of upwelling areas and indicators

Figure 2 shows the simulated and observed SST averaged over the period of SVU, June-September (JJAS), over 2009-2018. Low SST (< 29°C) simulated by SYMPHONIE and observed in OSTIA along and off the central Vietnam coast is
190   the signature of the SVU, and reveals the same areas of upwelling as Da et al. (2019) and Ngo and Hsin (2021). The coldest water around 109°E - 11.5°N (<27°C at the coast) corresponds to the coastal center of the upwelling. The coastal area of cold water (~28-29°C) extends south and north of this cold center, from 8.8°N, off the Mekong mouth, and to 15.5°N, along the Vietnamese coast. Cold water is also observed offshore, from 109°E to 114°E and from 10°N to 14°N. We therefore define four areas of upwelling, shown in Figure 2 (see caption for exact coordinates). BoxSC corresponds
195   to the well-known coastal upwelling that develops under the effect of the eastward jet, named SCU hereafter. BoxOF corresponds to the offshore upwelling, OFU. BoxNC shows the northern coastal area between 12°N and 15°N where the

upwelling develops less frequently and has been much less studied, named NCU hereafter. A fourth area of minimum SST is also visible both in observed and simulated summer SST off the Mekong Delta, in the wake of Con Dau Island between 8° and 10°N and 106.5°E and 109°E, named BoxMK hereafter. To our knowledge this upwelling, named MKU

200   hereafter, was not studied until now. It was however already visible in AVHRR SST data over 1991-2004 (Da et al. 2019, their Figure 1) and in SODA reanalysis SST over 1987-2008 (Fang et al. 2012, their Figure 5).

To examine the interannual variability of the upwelling over each area, we compute from our simulation a SST-based upwelling index for each box, following the methodology detailed in Da et al. (2019). First, for each upwelling area we

205   define the reference temperature T_{RefN} as the 2009-2018 average of SST over the reference box $refN$ and over June to September (JJAS). The reference box is taken as the area next to the upwelling box not impacted by surface cooling. Reference boxes are shown in Figure 2. The threshold temperature below which upwelling happens, $To = 27.6°C$, is defined from the frequency of occurrence of cold surface water as the temperature allowing to cover the largest number of upwelling occurrences but avoiding to consider cold water advected between areas. To estimate the strength of the

210   upwelling over the area $boxN$, we define the daily index of upwelling :

$$UI_{d,boxN}(t) = \frac{\iint_{(x,y) in\ boxN\ so\ that\ SST(x,y,t)<To}(T_{refN}-SST(x,y,t)).dx.dy}{A_{boxN}} \tag{1}$$

where A_{boxN} is the size of $boxN$. We also define the yearly index :

215

$$UI_{y,boxN} = \frac{\int_{JJAS} UI_{d,boxN}(t)dt}{ND_{JJAS}} \tag{2}$$

where ND_{JJAS} is the duration of the JJAS period. To examine the spatial distribution of the upwelling, we also introduce a spatially dependent index of upwelling :

220

$$UI_{S,boxN}(x,y) = \frac{\int_{t\ in\ JJAS\ so\ that\ SST(x,y,t)<To}(T_{refN}-SST(x,y,t))dt}{ND_{JJAS}} \tag{3}$$

3. Model evaluation

3.1.   Representation of surface circulation and hydrological characteristics

225   Figure 3 shows the time series of climatological monthly and interannual yearly averages of simulated and observed SST, SSS and SLA averaged over the VNC domain. The normalized root-mean square error of a simulated time series compared to an observed time series is computed as $NRMSE = \frac{\sqrt{\frac{1}{N}(\sum_{i=1}^{n}(S_i-O_i)^2)}}{O_{max}-O_{min}}$ where S_i and O_i are respectively the simulated and observed values, and O_{max} and O_{min} the maximum and minimum observed values. Figure 4 shows the maps of winter and summer climatological average over 2009-2018 of observed and simulated SST, SSS and SLA.

230

Ocean Science
Discussions

3.1.1.   Annual Cycle and seasonal variability

The simulated seasonal cycle of SLA is in very good agreement with AVISO observations (Figure 3e), with a 1.0 correlation coefficient (p < 0.01) and a 6% NRMSE. It is maximum in November-January and minimum in June-July, in agreement with studies made from TOPEX/Poseidon altimeter data on the seasonal variability of SLA over the SCS

235   between 1992 and 1997 by Shaw et al. (1999) and Ho et al. (2000). Winter and summer SLA spatial patterns are realistically reproduced (Figure 4,i,j,k,l), with highly significant spatial correlations between simulated and observed fields (R>0.98). As explained in the Introduction, northeast monsoon winds induce a basin-wide cyclonic geostrophic circulation in winter. In summer, southwest monsoon winds induce a globally anticyclonic geostrophic circulation with a northward alongshore current. At a finer spatial scale, this current is composed of several gyres, in particular two

240   anticyclonic (AC) gyres centered at ~11°N and ~16°N and a cyclonic (C) gyre centered at ~13°N. The 11°N AC and 13°N C gyres form the well-known dipole and associated eastward jet (Wyrtky 1961, Xu et al. 1982, Fang et al. 2002, Xie et al. 2003,2007, Chen and Wang 2014, Li et al. 2014, 2017).

The seasonal cycle of SST over the region is very well reproduced by the simulation (Figure 3a). The bias compared to

245   OSTIA data is equal to 0.08°C on average, and varies between 0.02°C in winter and 0.09°C in summer, with a 2% NRMSE and a highly statistically significant correlation (1.0, p<0.01). Under the influence of Southeast Asia Monsoon, SST is maximum in May-June and minimum in January-February. This is consistent with Siew et al. (2013), who characterized the monthly climatological SST in the area from HadISST observations and 10 coupled model runs over the period 1961-2000. SST spatial patterns are also realistically simulated, with highly significant spatial correlations

250   between simulated and observed fields (Figure 4a,b,c,d, R=0.99 in winter and 0.85 in summer). In winter, the cold atmospheric fluxes and basin wide cyclonic circulation result in a strong meridional SST gradient, with coldest waters in the north and a cold tongue (SST< 26 °C) extending southward along the Vietnamese coast. In summer, the upwelling developing along the Vietnamese coast and extending offshore is clearly visible from the SST minimum (<28°C) on observed and simulated datasets. Though SYMPHONIE is overall in very good agreement with OSTIA in terms of spatial

255   variability and temperature range, it however slightly overestimates the observed surface cooling in very coastal areas near Hainan and southern Vietnam coasts. Piton et al. (2021) suggested that this surface cooling could be induced by tides. This difference could also be partly explained by the SST smoothing in OSTIA, as shown by Woo et al. (2020).

The simulated SSS over the VNC domain follows well the observed SMOS SSS (Figure 3b), with a highly statistically

260   significant correlation (0.89, p<0.01). Our simulation shows a fresh bias (-0.30 on average, from -0.22 in winter to -0.36 in summer), and an associated NRMSE of 0.76. This salinity difference could be due to the coarse resolution of SMOS (28 km), but also to an overestimation of atmospheric freshwater flux in the atmospheric forcing. Spatial patterns are well reproduced, with highly significant spatial correlations between observed and simulated SSS fields (0.84 in winter and 0.88 in summer, p<0.01, Figure 4e,f,g,h). Both simulation and data show low SSS over the Gulf of Thailand and the

265   northwestern Gulf of Tonkin, associated with the strong river and atmospheric freshwater fluxes. In the northeastern SCS, they show high SSS round the year, due to the influence of water entering through the Luzon Strait from the Western Pacific Ocean (Qu et al. 2000; Zeng et al. 2016).

Ocean Science
Discussions

3.1.2. Interannual variability

270 The interannual variability of SLA is very well simulated, with a 0.94 (p<0.01) correlation coefficient and a 0.13 NRMSE compared to AVISO dataset (Figure 3f). Both observed and simulated datasets show minimum values in 2009, 2011 and 2015, and maximum in 2010, 2012 and 2013, with an amplitude of ~3-4 cm.

The interannual variability of SST is also very well simulated, with a 0.95 (p<0.01) correlation coefficient and a 0.13
275 NRMSE compared to OSTIA dataset (Figure 3b). SST shows strong variations over the period, with a 1°C difference between the coldest (2011, 27.5°C) and warmest (2010, 28.5°C) years. As shown by Yu et al. (2019) over the period 2003-2017, those interannual variations are strongly related to ENSO : the 2010 and 2015-2016 El Niño events induce SST maxima, while the 2011 La Niña event induces a SST minimum.

280 Simulated interannual SSS time series shows a statistically significant correlation (0.80, p<0.01) and a 0.48 NRSME compared to SMOS observations (Figure 3d). Both model and data show an increase between 2012 and 2016, also observed by Zeng et al. (2014, 2018). Through a budget analysis based on a SCS 4 km SYMPHONIE configuration over the SCS, Trinh (2020) attributed this salinification to the rainfall deficit during this period.

285 ### 3.2. Representation of hydrological characteristics and vertical distribution of water masses, at the daily to interannual scales

We use ARGO, GLIDER, IO-18 and ALIS-TSG datasets to evaluate the ability of the model to reproduce water masses over the VNC domain, from the regional open-sea scale to the coastal scale. For that, we examine T-S diagrams built from ARGO (Figure 5a), GLIDER (Figure 5b) and IO-18 (Figure 5c) observations and colocalized SYMPHONIE outputs.
290 At the regional scale, ARGO data cover the whole open-sea region over 2009-2018. The hydrological characteristics and vertical distribution of water masses defined by Uu and Brankard (1997) and Dippner et al. (2011) (see Figure 5a) are overall very well simulated, with very similar contours of simulated and observed scatterplots. First, it reproduces the whole range of surface water masses, with salinity varying between 32 and 34 and temperature between 20°C and 30°C : the fresh MKGTW (Mekong and Gulf of Thailand Water), the more saline OWW (Offshore Warm Water) and OSW
295 (Offshore Salty Water) and the colder ECSW (East China Sea Water). Second, it reproduces realistically the observed salinity maximum (reaching ~34.8) that corresponds to the Maximum Salinity Water (MSW, between 100 and 200m depth) and the salinity minimum (reaching ~34.4) that corresponds to the Permanent Thermocline Water (PTW, at ~400 m depth). Last, it reproduces correctly the Deep Water (DW) mass, with a cold average bias (0.1°C) and a negligible salinity bias (<0.01).

300

GLIDER data were collected between January and May 2017, i.e. during the period of northeast monsoon and the transition period to the southwest monsoon. They cover the regional to coastal scales (Figure 1b). During this 9th year of the simulation, the model is able to reproduce in detail the observed temperature and salinity profiles (Figure 5b), though with slightly higher biases of salinity (up to 0.15) and temperature (up to 0.4°C) than for ARGO dataset. In particular it
305 reproduces realistically not only the deep water masses down to 1000 m depth, but also the 2 branches of surface water masses that were sampled by the glider : the fresher branch (SSS<34.5) observed at the beginning of the glider cruise south of 16°N, and the warmer branch (reaching 20°C) observed at the end of the cruise north of 17°N (see Figure SM1 that shows the observed and simulated SSS and SST along the trajectory). SYMPHONIE is therefore able to capture the

310   variability of water masses over the winter to summer transition period, from the coastal to more open-sea area, without producing a significant drift after more than 8 years of simulation.

IO-18 and ALIS data were collected during the period and over the region of upwelling, respectively in 2014 and 2018. Figure 6 shows the values of observed and colocalized simulated sea surface temperature and salinity along the ALIS-TSG trajectory, and their bias. The high frequency variability of SST and SSS recorded by the TSG along the ALIS

315   trajectory during summer 2014 is very well simulated, with a 0.89, resp. 0.93, correlation between observed and simulated time series. In particular both observed and simulated outputs clearly reveal the surface cooling (by more than 1 °C, with water colder than 28°C) and saltening (sith salinity reaching 34) observed at the end of June - beginning of July 2014 in the SVU area. IO-18 cruises covered both the shallow shelf area (8 stations, Figure 1) and the coastal to offshore upwelling area (10 stations) during summer 2018. The coastal shallow region, submitted to the influence of the Mekong freshwater,

320   shows warm (> 27°C) and fresh (<34) water, corresponding to the nearly horizontal branch of the T-S diagram (Figure 5c). In the deeper offshore region the water is much colder and saltier (<20°C and > 34.5, the nearly vertical branch). Again, the model reproduces well the temperature and salinity characteristics of both types of water masses and areas. It is therefore able to reproduce the diversity of profiles in the coastal and offshore upwelling region without any significant bias, even after 9 years of simulation.

4. Interannual variability of the South Vietnam Upwelling

Our high-resolution simulation reproduces realistically the surface circulation and the hydrological characteristics of water masses at the surface and over the water column, and their spatial (from shelf to open sea) and temporal (seasonal to interannual) variability. Based on this 10-years simulation, we examine in detail the functioning and interannual variability of SVU over the 4 regions of interest : southern (BoxSC) and northern (BoxNC) coasts, offshore region

330   (BoxOF) and Sunda shelf (BoxMK). Figure 7 shows the time series of yearly upwelling index over the period 2009-2018 for the 4 boxes. Table 2 shows the mean and standard deviation of those time series, the coefficient of variation CV defined as the ratio between the standard deviation and mean, and correlations between time series of significant factors, in particular upwelling yearly indexes and summer wind. Figure 8 shows for each year of the simulation the maps of spatial upwelling index $UI_{s,boxN}$ and of JJAS averaged surface current and of its vorticity.

4.1. BoxSC

As already shown in previous studies cited above, the SCU develops along the Vietnamese coast between 10.5°N and 12°N in the area of convergence between the northern southward and southern northward boundary currents (Figure 8). These currents are associated with respectively the northern cyclonic and southern anticyclonic gyres, and their convergence results in the eastward jet.

340

SCU shows a significant interannual variability, though the lowest of the 4 boxes (CV = 53%, Table 2). Previous studies suggested that the interannual variability of upwelling in the coastal area of Vietnam is mainly triggered by the interannual variability of the summer averaged wind stress that induces Ekman transport (Chao et al. 1996, Dippner et al. 2007, Da et al. 2019, Ngo and Hsin 2021). Figure 7 shows the yearly time series of the average over each box and over JJAS of

345   wind stress, $WS_{JJAS,boxN}$. First, time series of the summer wind over BoxSC and over BoxOF are almost equal (Figure 7) and completely correlated (0.99, p<0.01, Table 2). The intensity and interannual variability of summer wind over boxSC is thus completely driven by the large-scale wind. Second, in 2010, $WS_{JJAS,SC}$ is minimum and significantly weaker than

Ocean Science
Discussions

Open Access

EGU

for the other years and almost no upwelling develops over BoxSC ($UI_{y,SC} \simeq 0.05$ °C, one order of magnitude smaller than the average). Conversely, when wind stress peaks in 2018 ($WS_{JJAS} \simeq 0.11$ N.m^{-2}) SCU also reaches its maximum intensity
350 ($UI_{y,SC} \simeq 1.49$ °C, about twice stronger than the average). We moreover obtain a highly significant correlation between $UI_{y,SC}$ and $WS_{JJAS,SC}$ (R=0.85, p<0.01, Table 2). This confirms that the interannual variability of SCU is driven at the first order by the intensity of the summer averaged monsoon wind.

355 Other factors however modulate the summer wind-induced interannual variability of SCU.

The first factor is the daily to intraseasonal variability of wind forcing. For example, even though 2009 and 2012 show the same average summer wind over BoxSC ($WS_{JJAS,SC} \simeq 0.09$ N.m^{-2}, Figure 7), SCU is 23% weaker in 2009 ($UI_{y,SC} \simeq 0.73$ °C, Figure 7) than in 2012 ($UI_{y,SC} \simeq 0.95$ °C). Figure 9 shows the time series of daily upwelling index $UI_{d,SC}$ and of daily average wind stress over boxSC for 2009 and 2012 (and 2011). For all the years, the development of upwelling over
360 BoxSC is related to the daily chronology of wind, with upwelling peaks occurring during wind peaks. The wind over BoxSC is stronger in July and September for 2009, vs. June and August for 2012. In 2012, the SCU consequently develops strongly in June, and persists throughout the summer, especially in August. Conversely in 2009 it mainly develops in July, and does not persist in August due to the weaker wind during this month. The daily to intraseasonal variability of wind forcing during the summer therefore modulates the SCU interannual variability.

365 High frequency wind forcing however does not explain all the differences. The coastal circulation and mesoscale dynamics also contribute to the modulation of the SCU intensity. For example, 2011 shows the second strongest SCU ($UI_{y,SC} \simeq 1.35$ °C, Figure 7), ~90% stronger than for 2009 and ~40% than for 2012. However, $WS_{JJAS,SC}$ in 2011 ($\simeq 0.09$ N.m^{-2}, Figure 7) is ~10% lower than in 2009 and 2012. Moreover, wind stress in June 2011 is not stronger than in June
370 2009 and 2012, neither in average nor in terms of high frequency peaks (Figure 9). However, SCU develops strongly in June 2011 and persists throughout the summer, reaching much higher values than in 2009 and 2012. This suggests that the higher upwelling intensity in 2011 is not related to a difference in summer wind, neither in average nor at the daily to intraseasonal scales. Instead, it is related to the background circulation (Figure 8). 2009 and 2012 show the double AC/C dipole and associated eastward jet at ~12°N classically described in the literature. Instead, 2 AC/C dipoles develop during
375 summer 2011 along the Vietnamese coast, one southern than for the other years, and one northern. They result in 2 eastward jets departing respectively from ~11°N and 14°N. This results in an overall offward current along the coast, hence in a wider coastal upwelling. The background coastal circulation and mesoscale structures are therefore a second factor that modulates the SCU interannual variability.

4.2. BoxOF

380 The interannual chronology of wind stress and summer upwelling over BoxOF is very similar to that of BoxSC (Figure 7), with a minimum in 2010 and a maximum in 2018. $UI_{y,SC}$ and $UI_{y,OF}$ are highly significantly correlated (0.73, p=0.02, Table 2). This suggests that the interannual variability of OFU and of SCU are driven by the same factors. The summer wind strength indeed is a key factor involved in OFU interannual variability : $UI_{y,OF}$ and $WS_{JJAS,OF}$ are highly statistically significantly correlated (R = 0.77, p=0.01, Table 2) though slightly less than for SCU (0.85). OFU shows the strongest
385 interannual variability (CV$\simeq$126%, Table 1), explained partly by the very strong OFU in 2018 compared to other years, related to the strong wind in summer 2018 (Figure 7).

Da et al. (2019) simulated an Ekman pumping-related OFU that develops under the influence of strong positive wind curl, that can be enhanced (weakened) if cyclonic (anticyclonic) mesoscale structures associated with positive (negative) surface current vorticity are present in the area of positive wind curl. The influence of those chaotic mesoscale structures explained the significant impact of OIV in OFU variability. Ngo and Hsin (2021) showed that OFU is stronger (weaker) for years of stronger (weaker) wind stress curl and large scale circulation (eastward jet and dipole). Figure 7 shows the time series of $\zeta_{+,OF}$, the spatial integral over BoxOF of the positive part of summer averaged relative vorticity. It integrates both the cyclonic activity north of the jet and the positive vorticity on the northern flank of the eastward jet (a more intense and narrow eastward current being characterized by a higher vorticity). $\zeta_{+,OF}$ is thus an indicator of the intensity of the summer circulation (dipole+eastward jet) in the offshore region. The interannual variability of this intensity is actually strongly induced by the variability of wind forcing : there is a highly significant correlation between time series of $\zeta_{+,OF}$ and $WS_{JJAS,OF}$ (0.89, p<0.01, Table 2).

Our high-resolution simulation confirms the link between the intensity of OFU and of summer offshore circulation and related vorticity. OFU indeed occurs mainly in areas of positive surface current vorticity : along the northern flank of the eastward jet and north of the jet as the result of mesoscale cyclonic structures (Figure 8). For example, wind is similar for 2014 and 2016 ($WS_{JJAS,OF}\simeq0.08$ N.m^{-2}, Figure 7), however OFU is about twice stronger in 2014 (0.06°C) than in 2016 (0.03°C). The difference can be explained by the mesoscale activity and eastward jet in the offshore area. In 2014, an intense cyclonic eddy forms north of the intense and marked eastward jet (Figure 8), and $\zeta_{+,OF}$ is twice larger (~2.6x10^{-6} s^{-1}, Figure 7) than in 2016 (~1.5x10^{-6} s^{-1}). In 2016 the jet is indeed wide and less intense and no cyclonic eddy develops. The significant correlation between time series of $UI_{y,OF}$ and $\zeta_{+,OF}$ (0.69, p=0.03, Table 2) quantifies this link between OFU intensity and the intensity of summer offshore circulation. $UI_{y,SC}$ is also significantly correlated with $\zeta_{+,OF}$ (0.60, p=0.07, Table 2), which confirms that SCU is stronger/weaker for years of intense/weak summer circulation off Vietnam coast.

For some cases, as suggested by Ngo and Hsin (2021), OFU can even be inhibited. In 2010 upwelling does practically not develop over BoxOF and BoxSC (Figure 7). The eastward offshore jet and dipole structure that are usually observed in summer do not exist during summer 2010 ($\zeta_{+,OF}$ ~0.5x10^{-6} s^{-1}, much smaller than for the other 9 years and four times smaller than the mean, Figure 7 and Table 1), and the alongshore current flows northward between 9°N and 16°N (Figure 8). Those circulation conditions prevent the formation of an offshore current and of the associated upwelling. For this year, extreme weak wind conditions as well as circulation background thus both prevent the development of upwelling. Factors other than summer wind intensity and summer circulation over the offshore area modulate the variability of OFU. For example, in 2018 both $WS_{JJAS,OF}$ (0.11 N.m^{-2}, Figure 7) and $\zeta_{+,OF}$ (3.4x10^{-6} s^{-1}) are only ~10% higher than in 2009 and 2012 (respectively 0.10 N.m^{-2} and 3.1x10^{-6} s^{-1}). However, $UI_{y,OF}$ in 2018 (0.32°C) is respectively 2.6 and 4.6 times larger than in 2009 (0.12°C) and 2012 (0.07°C), and 4 times higher than the average (0.09°C, Table 2). Comparatively, for BoxSC, $UI_{y,SC}$ in 2018 it is only ~2 times larger than the average value. Last, the correlation between $UI_{y,box}$ and $WS_{JJAS,box}$ is lower for BoxOF (0.77) than for BoxSC (0.85). This shows that other factors modulate the interannual variability of OFU, even more than for SCU.

The intraseasonal variability of wind is one of those factors. Figure 10 shows the time series of daily upwelling index $UI_{d,OF}$ and daily average wind stress over boxOF for 2009, 2012 and 2018. Wind stress peaks mostly occur in July and September in 2009, and in June and September in 2012. In contrast, in 2018, wind stress peaks occur in July and August, inducing a very strong upwelling during those months. The monthly averaged wind is consequently significantly stronger

430 in July and August 2018 than in July and August of the other years, and than in June and September 2018 (Figure 10). This suggests that OFU is stronger when wind peaks occur during the core of the summer season (July-August) than at the beginning (June) or end (September). The correlation of time series of $UI_{y,OF}$ with time series of July-August averaged wind stress over BoxOF is indeed higher (0.84, p<0.01, Table 2) than the correlation with JJAS wind stress (0.77, p<0.01), confirming this hypothesis. Conversely, for BoxSC, this correlation is weaker (0.70, p=0.03 for July-August vs. 0.85,

435 p<0.01, for JJAS, Table 2). The development of SCU occurs during the whole JJAS period as soon as the wind conditions are favorable, and is thus mainly induced by wind forcing which prevails on and drives circulation patterns. Summer wind forcing also appears to be one of the major factors inducing OFU. However, other factors, presumably related to a favorable combination of wind forcing and background circulation, favor its development during July-August more than June and September.

440 **4.3.   BoxNC**

Upwelling also develops, though to a weaker extent, along the northern part of the central Vietnam coast (BoxNC). $UI_{y,NC}$ shows a relatively strong interannual variability (71%, Table 2). We obtain no statistically significant correlation between $UI_{y,NC}$ time series and time series of the average wind stress, whatever the period and area of averaging (Table 2). Moreover we obtain no statistically significant correlation between $UI_{y,NC}$ time series on one hand and $UI_{y,SC}$ or $UI_{y,OF}$

445 time series on the other side (Table 2). This suggests that contrary to SCU and OFU, the interannual variability of NCU is not driven by the summer wind or the summer offshore circulation.

Examining into details the 10 summers of the simulation in Figure 8, we identify 4 main situations that prevent or favor the development of NCU. First, the inhibition of NCU can result from two opposite situations in terms of wind, offshore

450 circulation and upwelling intensity over the other boxes :

● Influence of a marked southward alongshore current : summers 2009, 2012, 2018. Those years show maxima of summer wind over the region (see $WS_{JJAS,OF}$, Figure 7) and of SCU and OFU intensity, but minima of NCU intensity (Figure 7). They are associated with a highly marked dipole and associated eastward jet, with a strong positive vorticity

455 over the offshore area (Figures 7,8). As explained above, those atmospheric and circulation patterns explain the strong SCU and OFU. Moreover, the strong northern cyclonic gyre induces a marked southward alongshore current over BoxNC, with a very weak offshore component. The southward alongshore current is indeed associated with a cyclonic hence divergent circulation, hence with a coastward component and a coastal downwelling. This circulation opposes the wind-induced circulation and inhibits the NCU.

460

● Influence of a marked northward alongshore current: summers 2010, 2013, 2017. NCU is weaker than average, and SCU and OFU are weaker than average (2010 and 2017) or close to average (2013) (Figure 7). For those 3 cases, summer wind over the region is weaker than the average or average (see $WS_{JJAS,OF}$, Figure 7). This results in weaker than average Ekman transport over the coast and pumping in the offshore region, and much weaker than the average (or even absent

465 in 2010) dipole and eastward jet (see $\zeta_{+,OF}$, Figure 7). Instead, an alongshore northward current with a very weak offshore component develops all along the Vietnamese coast (Figure 8). Those atmospheric and circulation patterns explain the weak OFU, SCU and NCU.

Second, the development of NCU can also result from two different situations:

470

- For some summers (2011, 2014, 2015), a secondary dipole develops north of the usual dipole structure (see the alternation of negative and positive vorticity between 12°N and 16°N, Figure 8). This results in the development of a second coastal area of convergence of northward and southward currents over BoxNC. In addition to the usual eastward jet, a secondary jet thus originates from the northern part of the coast, inducing a strong upwelling over BoxNC. This

475 situation does not seem to be related to the wind intensity : it occurs in case of strong wind and upwelling over BoxOF and BoxSC (2011 and 2014, Figure 7) as in the opposite case (2015). It is also not related to the intensity of summer offshore circulation, which is strong in 2014 (Figure 8) but weak in 2011 and 2015.

- 2016 is the last case : wind over the region, the dipole structure and eastward jet, and, consequently, SCU and OFU, are weaker than average (Figure 7). The eastward current is weaker but also wider than average, and an overall offshore

480 circulation is simulated over a large part of the area (Figure 8). This enhances the offshore advection of cold water from the coast and the development of a stronger than average NCU.

4.4.   BoxMK

The interannual chronology of wind stress over BoxMK is very similar to that of BoxOF and BoxSC (Figure 7) and $WS_{JJAS,MK}$ is highly significantly correlated with $WS_{JJAS,SC}$ (0.97, p<0.01, Table 2) and $WS_{JJAS,OF}$ (0.96, p<0.01). The

485 interannual variability of wind over BoxMK is therefore related to the intensity of the summer monsoon wind over the SVU region.

MKU shows the weakest mean value of the 4 boxes (0.07°C, Table 2), and a relatively strong interannual variability (CV=85%). The interannual chronology of MKU is very similar to that of OFU and SCU, with a minimum in 2010 and

490 a maximum in 2018 (Figure 7). $UI_{y,MK}$ is highly significantly correlated with $UI_{y,SC}$ (0.83, p<0.01, Table 2) and $UI_{y,OF}$ (0.92, p<0.01). MKU interannual variability is therefore likely driven by the same factors as OFU and, to a slightly lesser extent, SCU.

The summer wind strength and summer offshore circulation are indeed key factors involved in MKU interannual

495 variability. $UI_{y,MK}$ shows a highly statistically significant correlation with July-August wind over the region ($WS_{JA,OF}$: 0.82, p<0.01, Table 2). MKU intensity moreover shows highly statistically significant correlation with $\zeta_{+,OF}$ (0.74, p<0.01). This correlation is even higher than for SCU and OFU, suggesting an even stronger influence of summer offshore circulation (eastward jet and dipole) in MKU interannual variability.

500 In contrast with upwelling that develops over the 3 other areas, the position of MKU is very stable from one year to another (Figure 8). It develops in the area of positive vorticity along the western flank of the northeastward current that flows off the Mekong delta, and is stronger when this current is stronger. This current constitutes the western part of the southern anticyclonic gyre of the dipole and forms the eastward jet when it encounters the northern cyclonic gyre. Its intensity therefore varies interannually following the intensity of the summer offshore circulation, explaining the link

505 between MKU and the offshore circulation. However the spatial structure of currents in the MKU region is very stable from one year to another, contrary to what is obtained for the 3 other areas (Figure 8). This suggests that this spatial structure is strongly constrained by non-interannually-varying factors, including topography, and explains the stable position of MKU. BoxMK is indeed located on the shallow continental shelf, with depths varying from ~15 m at the coast to more ~ 200 m over the continental slope (Figure 2).

510

Those results show that MKU interannual variability is presumably driven by the summer monsoon wind and by the northeastward current, which is completely related to the intensity of the wind-induced summer offshore circulation. Moreover, bathymetry related mechanisms in BoxMK constrain the spatial structure of the currents and of MKU, which do not change interannually. For the 3 other boxes, the organization of mesoscale structures and associated vorticity and

515   of coastal circulation modulate the interannual variability of upwelling intensity induced by summer wind. This is not the case for BoxMK.

4.5.   Comparison of simulated and observed interannual variability

Ngo and Hsin (2021) produced the most recent and longest time series of observed intensity of upwelling over 3 of the areas studied here (SCU, NCU and OFU), using a SST-based upwelling index applied on a 0.25° dataset of satellite

520   observed SST over the period 1982-2019 (their Figure 4).

For SCU and OFU, the interannual variability of upwelling intensity over the period 2009-2018 is similar at the first order in the time series simulated by our model and observed by Ngo and Hsin (2021) (Figure 7). In particular their intensity is highest in 2018 and lowest in 2010. For SCU, 2011, 2012 and 2014 are more intense than the average in both simulated

525   and observed time series, and 2017 is much less intense than the average. For OFU, 2011 and 2012 are more intense than the average and 2013, 2015, 2016 and 2017 are less intense. However some years are significantly different in simulated and observed time series. 2015 SCU is stronger than average in observations vs. smaller in our simulation. 2009 OFU is lower than average in observations, vs. the 2nd highest in our simulation. Differences are stronger for NCU, with only 4 years in agreement. 2009 and 2012 show particularly weak (or non-existent) NCU, 2015 shows a strong NCU and 2011

530   an average NCU in both observed and simulated time series.

The low resolution of satellite observations, which are moreover hindered by the strong cloud cover over the region in summer (Gentemann et al. 2004) partly explains those differences, especially in the small coastal boxes BoxNC and BoxSC. They could also be due to the chaotic part of ocean dynamics, which were shown to modulate the wind-induced

535   variability of upwelling over BoxSC, BoxOF and BoxNC. Our results above suggest that this OIV could be stronger for BoxNC, whose interannual variability is more influenced by ocean dynamics than by wind, explaining the larger differences between simulated and observed NCU time series.

5. Conclusion

A configuration of the 3D ocean model SYMPHONIE based on the use of a polar grid (with a high-resolution going from

540   ~1km along the coast to ~4 km in the open sea) and of VQS vertical coordinate was implemented over the Vietnamese coast and offshore SCS to study specific questions over the region (ocean dynamics, impact on ecosystems, propagation of pollutions), taking into account the large range of scales of dynamical processes involved.

We first performed a 10-year simulation over the recent period 2009-2018. Simulated sea surface temperature, salinity

545   and height and vertical salinity and temperature profiles were compared with available satellite data and 4 sets of in-situ observations (ARGO floats (2009-2018), a glider campaign (2017) and 2 R/V campaigns (summers 2014 and 2018)). Those comparisons quantitatively showed the ability of the model to reproduce the ocean circulation and water masses over the region at different scales : from the daily to interannual and climatological scales and from the coastal to regional scales.

550

This simulation was then used to investigate the interannual variability of summer upwelling that develops along the Vietnamese coast. 4 regions of upwelling development were identified : the coastal upwelling, that develops along the southern (SCU) and northern (NCU) parts of the Vietnamese coast, the offshore upwelling (OFU), and an upwelling that develop on the Sunda shelf off the Mekong delta (MKU).

555 Our results confirmed at the first order the conclusions of Da et al. (2019) and Ngo and Hsin (2021) about the interannual variability of SCU and OFU intensity. This variability is primarily driven by the same processes. The intensity of summer wind stress and curl, which induces Ekman transport and Ekman pumping, is the driving factor at the first order. Moreover, the intensity of summer circulation in the offshore area, i.e. the dipole and associated eastward jet, which is actually also induced by the summer wind forcing, reinforces this wind-induced interannual variability.

560

The high resolution of the simulation analysed here moreover allowed to reveal and examine the role of other factors, in particular smaller spatial and temporal scales of atmospheric forcing and ocean circulation. First, our results show that the intensity of SCU and OFU is not only driven by the average summer wind, but also by its variability at higher frequency, daily to intraseasonal. For a given summer average wind intensity, SCU is stronger when wind peaks occur
565 regularly throughout the 4 months of the whole JJAS period, compared to situations where peaks occur only during some of the 4 months. Moreover, wind peaks of same intensity induce upwelling peaks of similar intensity, whatever their months of occurrence. In contrast, OFU is strengthened when wind peaks mainly occur during the July-August period. This could be due to a more intense offshore circulation (eastward jet and cyclonic gyre, which contributes more to OFU strength than for SCU) during this period, and will be examined in a future study. Second, mesoscale structures also
570 modulate the interannual variability of wind-induced SCU and OFU. Depending on the number of AC/C dipoles along the coast and on the position of the associated eastward currents, SCU can be more or less strong. Similarly, the occurrence, intensity and position of cyclonic eddies north of the eastward jet also modulates OFU intensity.

Our simulation also confirmed that upwelling can develop along the northern part of the Vietnamese coast, as shown for
575 the first time by Da et al. (2019) from AVHRR SST satellite data and from a 1/12° simulation for summer 1998. The high resolution of our simulation (~1 km over BoxNC) allowed to better understand which factors trigger the interannual variability of NCU. This variability is not driven by the same processes as SCU and OFU, i.e. intensity of summer wind and summer circulation, but can rather be explained by the interactions between wind and small mesoscale structures and circulation in the coastal area. In agreement with observations of Ngo and Hsin (2021), who concluded that conditions
580 favorable to SCU and OFU were unfavorable to NCU, and vice versa, we first identified 2 situations. They correspond to cases where strong (weak) summer wind and offshore circulation favorable (unfavorable) to OFU and SCU strengthen (weaken) alongshore currents and weaken (strengthen) offshore currents along the northern part of the coast, thus offshore advection of cold water that could result from Ekman transport, resulting in weak (strong) NCU. Second, we also identified situations where wind conditions favorable to SCU and OFU are also favorable to NCU, due to the development
585 of multiple dipoles and eastward jets ; and the opposite (unfavorable for the 3 areas), due to weak wind and to an alongshore northward current all along the coast. Similar summer wind conditions can therefore result in very contrasted NCU intensity, and conversely opposite wind conditions can result in similar NCU intensity.

Last, our study revealed that upwelling also develops offshore the Mekong delta, along the western flank of the
590 northeastward current. As for SCU and OFU, the interannual variability of MKU intensity is mostly driven by the interannual variability of the wind-induced summer circulation in the offshore region. However, contrary to what is

Ocean Science
Discussions

Open Access

concluded for SCU, OFU and NCU, it is hardly modulated by the influence of mesoscale dynamics of strong chaotic nature. The spatial structure of currents and upwelling over boxMK is indeed very stable, being presumably constrained by non-interannually-varying factors. Fang et al. (2012) also showed that this segment of the summer circulation is stable

595 at the interannual scale, whereas the northern and eastern parts are much more unstable. Detailed mechanisms involved in MKU functioning and variability, in particular bathymetry but also tides, will be examined in a future study.

Da et al. (2019) revealed through their 1/12° simulation the impact of OIV on interannual variability of upwelling, using an indicator integrated over the whole SVU area. Our results highlighted the contribution of high frequency and mesoscale ocean dynamics and coastal circulation of strong chaotic nature to the interannual variability of SCU, OFU, and more

600 particularly, NCU. Our high-resolution configuration will now be used to study the chaotic vs. forced component of ocean dynamics at different scales, and their impact on the daily and intraseasonal to interannual variability of the SVU over its different areas of development.

Last, this numerical tool can be coupled with biogeochemical models (Herrmann et al. 2014, 2017, Ulses et al. 2016) or

605 used for applied purposes such as pollution monitoring (Estournel et al. 2012, Masumoto et al. 2012, Belharet et al. 2016). It is openly available for the scientific community willing to investigate the functioning, variability and influence of ocean dynamics in the area.

Code and data availability

The SYMPHONIE model is available on the webpage of the SIROCCO group, https://sirocco.obs-mip.fr/. Outputs of the

610 simulation performed over the period 2009-2018 over the VNC configuration are freely available upon request to the authors.

Authors Contribution

To Duy Thai, Marine Herrmann and Claude Estournel designed the experiments and To Duy Thai carried them out, with the support of Thomas Duhaut and Patrick Marsaleix. Patrick Marsaleix, Thomas Duhaut and Claude Estournel developed

615 the model code. To Duy Thai, Trinh Bich Ngoc and Patrick Marsaleix worked on the model optimization. Bui Hong Long organized the IO-18 survey. To Duy Thai and Marine Herrmann prepared the manuscript with contributions from all co-authors.

845 **Figures**
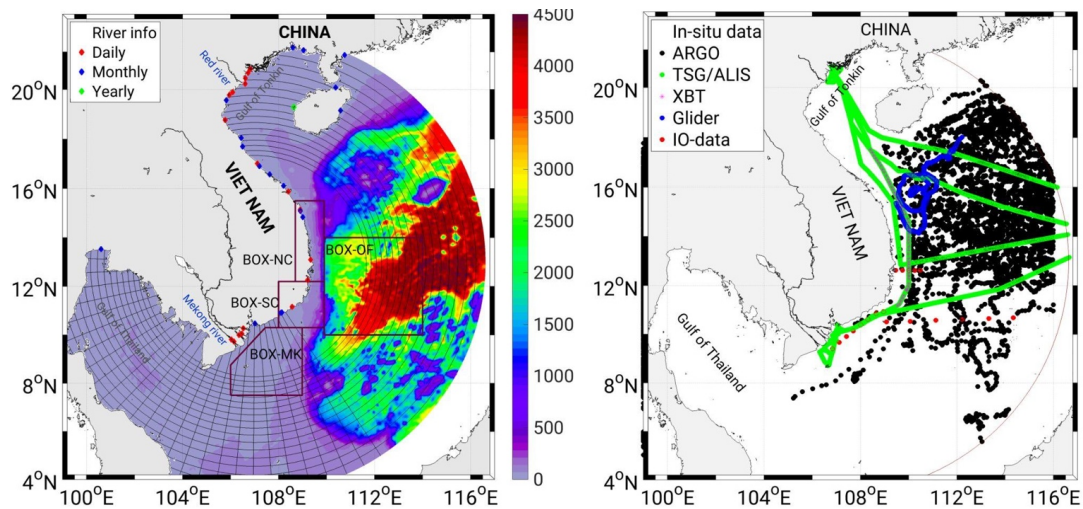

Figure 1. (Left) Characteristics of the orthogonal curvilinear computational grid (black lines, not all points are
shown for visibility purposes) and bathymetry (colors, m, *GEBCO_2014*) used over the VNC configuration of the

850 SYMPHONIE model. Dots show the location of rivers for which we used daily (red), monthly (blue) and yearly
climatology (green) discharge values. Black boxes show the location of the 4 boxes used for the study of VNU.
(Right) Location of *in-situ* data available over the VNC domain: ARGO buoys (black), ALIS R/V campaign
(TSG: green), IO-18 data (red), and glider data (blue).
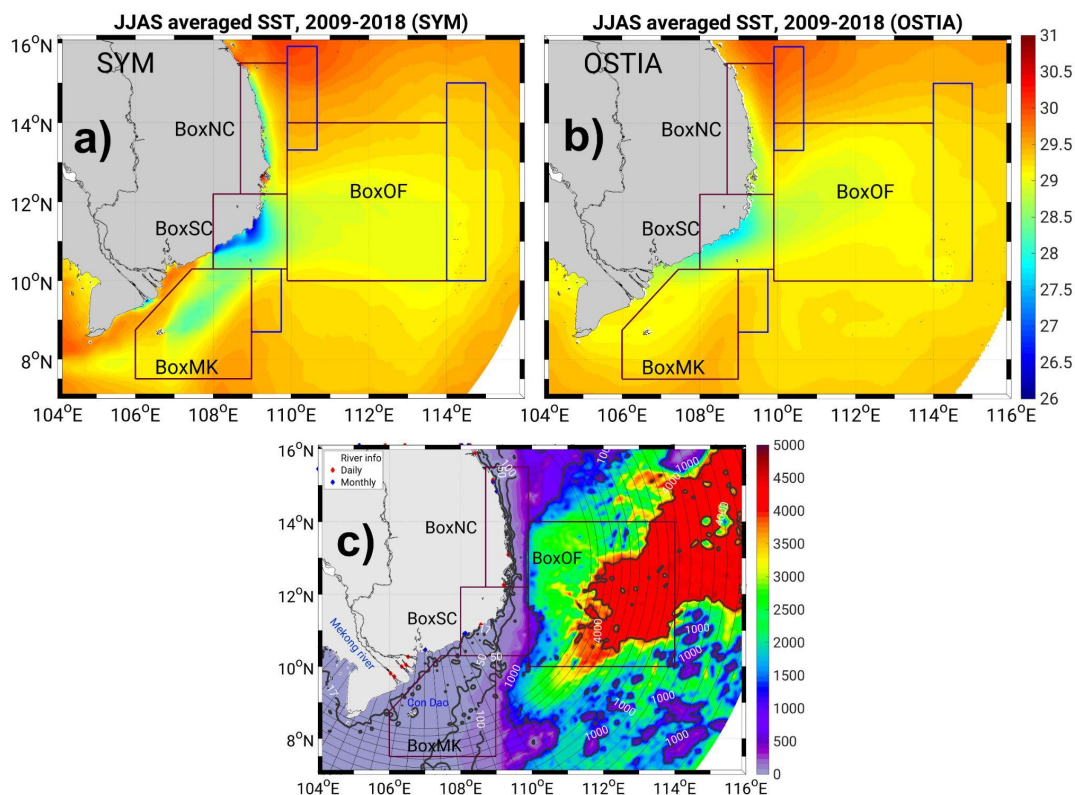

855

**Figure 2 : JJAS average over 2009-2018 of simulated (a) and observed (b) SST (°C) over the SVU region, and (c)
bathymetry of the SVU region. Black boxes show the 4 upwelling areas, and blue rectangles in a,b show the
corresponding reference boxes. Coordinates of the boxes : BoxNC (12.2-15.5ºN; 108.7-109.9ºE), BoxSC (10.3-
12.2ºN; 108-109.9ºE), BoxOF (10-14ºN; 109.9-114ºE), BoxMK (at depth > 17m, 7.5-10.3ºN; 106-109ºE). Ref$_{NC}$ (13.3-
15.9ºN; 109.9-110.7ºE), Ref$_{SC\&MK}$ (8.7-10.3ºN; 109-109.7ºE), Ref$_{OF}$ (10-15ºN; 114-115ºE)**

Figure 3. Climatological monthly time series (left) and interannual yearly time series (right) of simulated (red) and observed (blue) SST (a,b, ºC), SSS (c,d) and SLA (e,f, m) averaged over the VNC domain. Correlation (correlation coefficient R and p-value P), NRMSE and bias of simulated vs. observed values are indicated.

Discussions
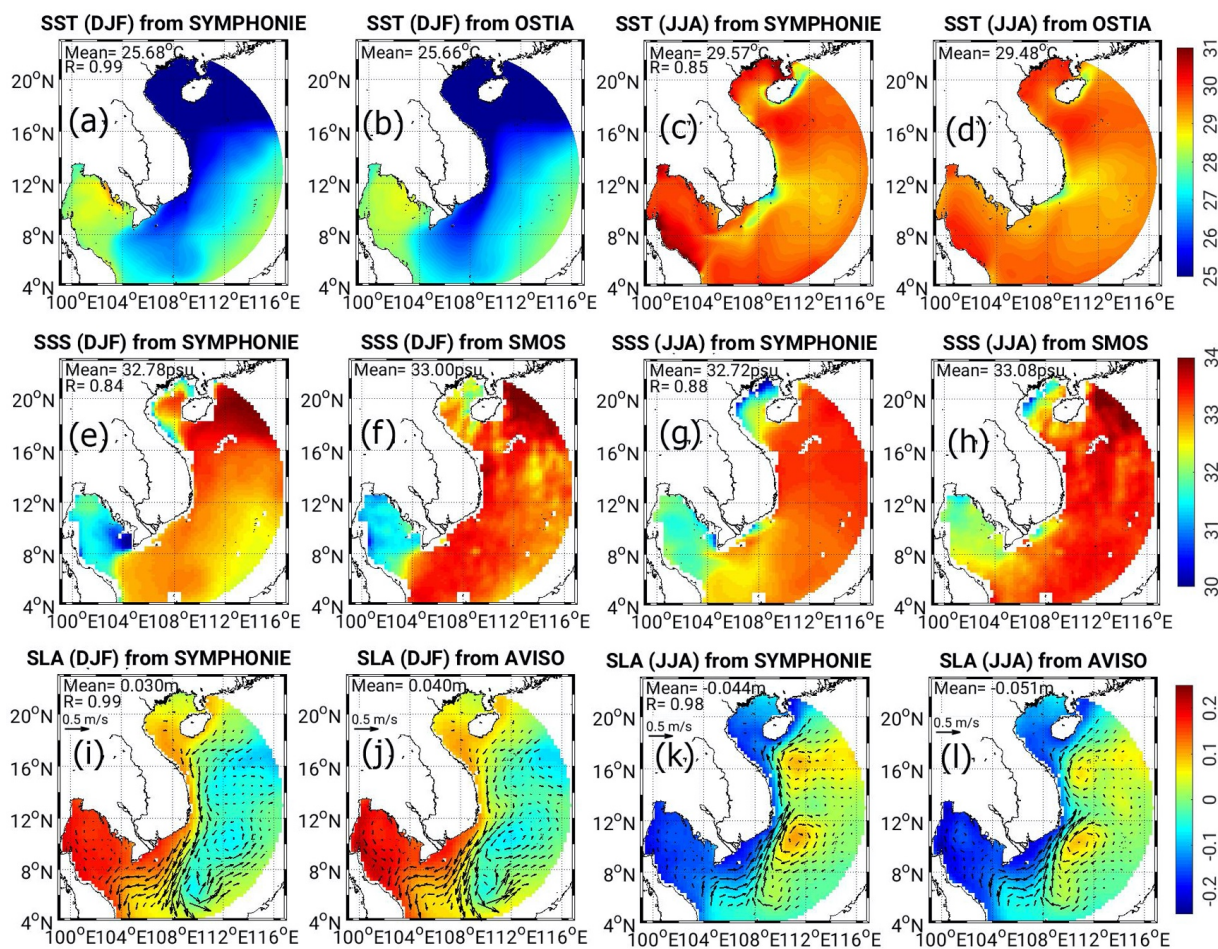

Figure 4 : Spatial distribution of simulated and observed winter (DJF) and summer (JJA) climatological averages of SST (a,b,c,d, °C), SSS (e, f, g, h), SLA (i,j,k,l, m) and total surface geostrophic current (m.s^{-1}), and spatial correlation coefficient R (here the p-value is always smaller than 0.01)

875
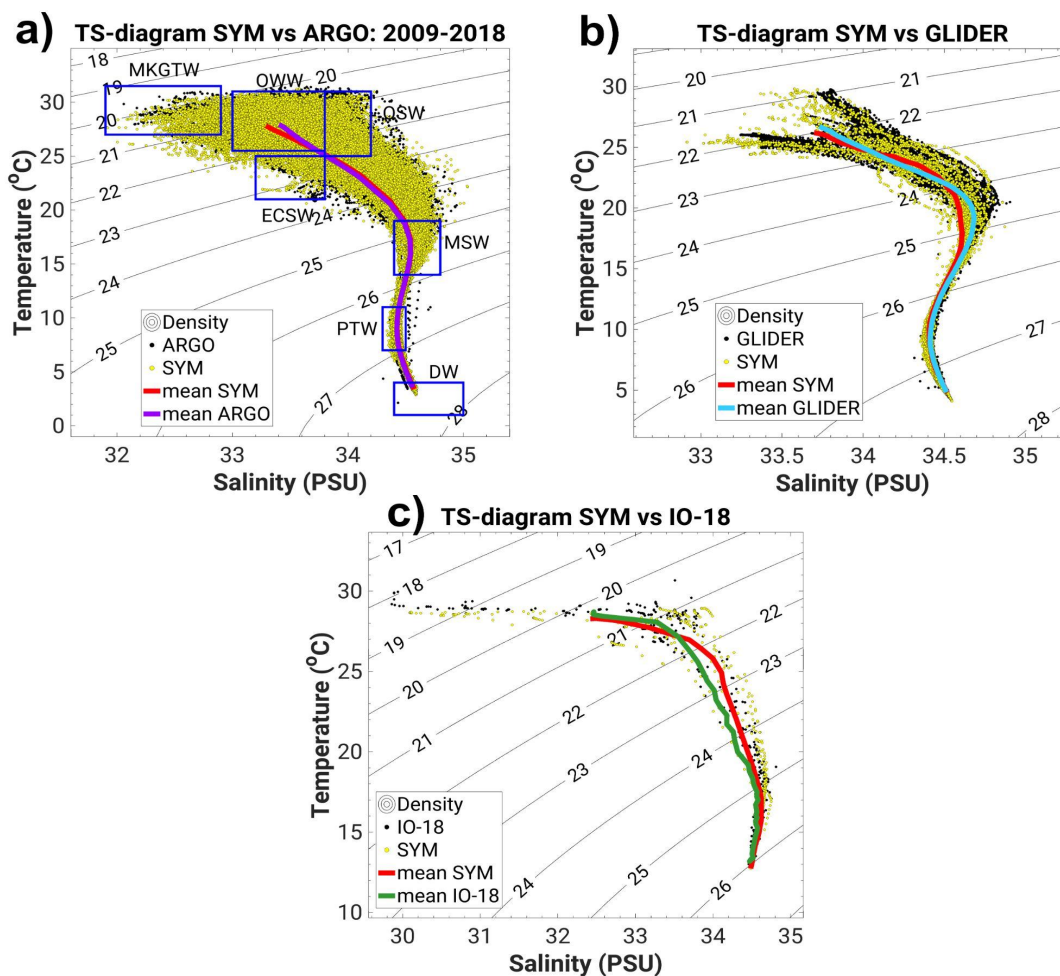

Figure 5 : TS-diagram built from ARGO (a, black dots and purple for mean), GLIDER (b, black dots and cyan for mean), IO-18 (c, black dots and green for mean) observations and from SYMPHONIE (yellow dots and red for mean) colocalized outputs. Blue rectangles represent water masses in the SCS (Uu and Brankard 1997, Dippner et al. 2011) : MKGTW (Mekong & Gulf of Thailand Water), OWW (Offshore Warm Water), OSW (Offshore Salty Water), ECSW (East China Sea Water), MSW (Maximum Salinity Water), PTW (Permanent Thermocline Water), DW (Deep Water).

Figure 6 : Values of SST (top) and SSS (bottom) from (a,d) ALIS-TSG trajectory during summer 2014 and from (b,e) SYMPHONIE colocalized outputs, and (c,f) bias between SYMPHONIE and ALIS-TSG.
Figure 7 : Interannual time series of normalized yearly upwelling index (top), average JJAS (middle) and JA (bottom) wind stress (N.m⁻²) over each upwelling box (BoxNC: purple ; BoxSC: blue; BoxOF: pink; BoxMK: green). The black dashed curve shows the integrated positive summer surface current vorticity over BoxOF (s⁻¹).

**Figure 8 : Maps of spatial yearly upwelling index (°C, a,b,c,d,i,j,k,l,q,r) and of speed and direction (arrows, m.s⁻¹) and vorticity (colors, s⁻¹) of JJAS averaged surface current (e,f,g,h,m,n,o,p,s,t) for each year of the simulation.**
