Abstract. Planktonic food-webs were studied contemporaneously in a mesoscale cyclonic (upwelling, ~13 months old) and an anti-cyclonic (down-welling, ~2 months old) eddies, as well as in an uninfluenced-background situation in the oligotrophic southeastern Mediterranean Sea (SEMS) during late summer 2018. We show that integrated nutrients concentrations were higher at the cyclone compared to the anti-cyclone or the background stations by 2-13 fold. Concurrently, *Synechococcus* and *Prochlorococcus* were the dominant community genus abundance-wise in the oligotrophic anti-cyclone (~300x10^{10} cells m^{-2}). In the cyclone, pico- and nanoeukaryotes such as dinoflagellates, Prymnesiophyceae and Ochrophyta contributed substantially to the total phytoplankton abundance (~14x10^{10} cells m^{-2}) which was ~65% lower in the anti-cyclone/background stations (~5x10^{10} cells m^{-2}). Primary production was highest in the cyclonic eddy (191 mg C m^{-2} d^{-1}) and was 2-5 fold lower outside the eddy area. Heterotrophic prokaryotic cell-specific activity was highest in the cyclone (~10 fg C cell^{-1} d^{-1}), while the least productive cells were found in the anti-cyclone (4 fg C cell^{-1} d^{-1}). Total zooplankton biomass in the upper 300 m was tenfold higher in the cyclone compared with the anti-cyclone or background stations (1337 vs. 112-133 mg C m^{-2}, respectively). Copepod diversity was much higher in the cyclone (44 species), compared to the anti-cyclone (6 small-size species). Our results highlight that cyclonic and anti-cyclonic eddies show significantly different community compositions and food-web dynamics in oligotrophic environments, with cyclones representing productive oases in the marine desert of the SEMS.

Running page head: Cyclone and anticyclone eddies affect plankton

1 Introduction

The southeastern Mediterranean Sea (SEMS) is an ultra-oligotrophic marine system (Berman et al., 1984) with low and patchy standing stocks of phytoplankton (Christaki, 2001; Efrati et al., 2013) and zooplankton (Pasternak et al., 2005; Siokou-Frangou et al., 2002). Phytoplankton are bottom-up controlled by N and P (Tanaka et al.,
and heterotrophic bacteria are limited by P (Sala et al., 2002; Thingstad et al., 2005; Zohary and Robarts, 1998), dissolved organic P (DOP, Van Wambeke et al. 2002; Djaoudi et al. 2018; Sisma-Ventura and Rahav 2019) and/or dissolved organic C (DOC, Hazan et al. 2018; Rahav et al. 2019). Phytoplankton is mostly comprised of cyanobacteria and pico-sized microbial eukaryotes with a high surface-area-to-volume ratio (Berman-Frank and Rahav, 2012; Ignatiades et al., 2002) that enables a faster nutrient uptake from the environment (Campbell and Vaulot, 1993). The low phytoplankton standing stocks lead to low primary production rates of 32-60 gC m$^{-2}$ y$^{-1}$ (López-Sandoval et al., 2011; Psarra et al., 2000). Zooplankton biomass is usually coupled with that of the phytoplankton and is mostly comprised of mesozooplankton that feed on pico-phytoplankton (Dolan and Marrasé, 1995; Pitta et al., 2001) or other mesozooplankton (Christou, 1998; Pasternak et al., 2005).

Alterations in plankton biomass or activity from their typically-low values can be found episodically in the SEMS at distinct hydrologic discontinuities such as cyclonic (upwelling) and anticyclonic (down-welling) eddies (Christaki et al., 2011; Groom et al., 2005; Rahav et al., 2013). These geostrophically balanced mesoscale structures can span tens to hundreds of kilometers in diameter (Groom et al., 2005; Robinson and Golnaraghi, 1994). These high-energy eddies may retain plankton communities over time-scales of weeks to months (Christaki et al., 2011; Menna et al., 2012; Rahav et al., 2013) and affect limiting nutrient levels at the euphotic zone (Condie and Condie, 2016). Therefore, the transport of potential and kinetic energy, nutrients and biota by eddies (cyclonic or anti-cyclonic) may alter phytoplankton and zooplankton biomass and activity (Allen et al., 1996; Falkowski et al., 1991).

In this study, we report the results of physical, chemical and biological samplings of two contrasting sites in the SEMS deep waters: cyclonic and anti-cyclonic eddies, as well as a background, uninfluenced station. We sampled these stations at the end of summer when the most oligotrophic conditions prevail in the photic layer (Kress et al., 2014; Rahav et al., 2019). We hypothesized that the upward advection of deep, and relatively cold nutrient-rich water within the cyclonic eddy enhance primary production, as well as the biomass of picoeukaryotes and zooplankton. On the contrary, down-welling circulation at the anti-cyclonic eddy yields ultra-oligotrophic conditions, even more than...
those of the background waters of the SEMS, leading to low phytoplankton biomass and production, the predominance of cyanobacteria, and low zooplankton biomass.

2 Methods

2.1. Study area and seawater collection

Water samples were collected during 9-11 October 2018 on-board the R/V Bat-Galim in three distinct water habitats: 1) Core of an anti-cyclonic eddy (Lat. 32.14 N, Lon. 33.59 E); 2) Core of a cyclonic eddy (Lat. 33.16 N, Lon. 33.86 E); and 3) A station uninfluenced by eddy circulation (hereafter referred to as ‘background’, Lat. 32.95 N, Lon. 34.46 E) (Figure 1A). The eddy’s core locations were determined a few days prior to the cruise and were updated until the morning of the cruise by maps created with the Angular Momentum Eddy Detection and tracking Algorithm (AMEDA) (Le Vu et al., 2018) applied on AVISO/CMEMS Sea Surface Height (SSH) data, which were produced especially for this mission. This algorithm tracks individual eddies and accounts for successive merging and splitting incidents between eddies. It also corrects for cyclostrophic balance of the surface velocity field, which allows a better representation of intense eddies (Ioannou et al., 2019). A more detailed characterization of the physical structure of the water column inside/outside the different cores was collected during the cruise and a few days afterward using a SeaExplorer glider equipped with temperature and salinity sensors (see below). The cruise was part of a cooperation with the ‘Pelagic Ecosystem Response to dense water formation in the Levant’ (PERLE) campaign, which is one of the three operations of the MERMEX (Marine Ecosystem Response in the Mediterranean EXperiment, https://mermex.mio.univ-amu.fr/) project. As such, it coincided with the project’s standard sampling protocols.

Seawater was sampled using Niskin bottles (8 L each) mounted on a rosette equipped with a CTD (Seabird 9 Plus) and a fluorometer (Sea-Point). Five to six water depths were sampled in each station which represented the main oceanographic features within the water column derived from real-time CTD and fluorometer data: the surface (2 m), the bottom of the mixed layer depth (30-60 m), the deep chlorophyll-a area (60-165 m), and bottom of the photic layer (180 m). An additional offshore station uninfluenced by eddy circulation (station THEM01) was sampled in a parallel cruise at the SEMS on the
same date as our study in larger details (11 depths within the photic layer, Reich et al., 2022). The chemical and chlorophyll-\(a\) profiles were not significantly different between the THEM01 and our background stations (Kruskal-Wallis One Way Analysis of Variance on Ranks, \(P>0.05\), Figure S1), thus giving credibility to our measurements which comprised only 5-6 depths at the photic layer. Meso-zooplankton were sampled using vertical WP2 hauls (Ø-57cm, 50-\(\mu\)m mesh-size, Hydro-Bios, Germany) hoisted at 0.5 m s\(^{-1}\) from 300 m to the water surface during nighttime (19:00-06:00). The southeastern Mediterranean Sea is an extremely oligotrophic region, with very low zooplankton densities, especially in the large-size fraction (Koppellmann et al., 2009). It was therefore stressed that the standard 200-\(\mu\)m is underestimating the mesozooplankton abundance and community structure in this region (Feliú et al., 2020) and therefore we used the 50-\(\mu\)m mesh-size. Filtered volume was measured using a mechanical flow meter (Hydro-Bios, Germany). The raw oceanographic data is publicly available at the ISRAMAR oceanographic database website (isramar.ocean.org.il).

2.2. SeaExplorer glider mission to characterize the physical characteristics of the water column (upper 700 m) within and outside the cores area

An autonomous underwater vehicle (SeaExplorer glider, ALSEAMAR) equipped with a SeaBird CTD was deployed at the southernmost sampling station (at the core of the anticyclone). The glider collected the temperature and salinity characteristics across the upper 700 m in a very high spatiotemporal coverage during ~18 days. The glider performed a total of 146 dives on its route northwards, yielding 292 quasi vertical profiles (see the glider track in Figure 1A).

2.3. Inorganic nutrients

Nutrient concentrations were determined using a three-channel segmented flow auto-analyzer system (AA-3 Seal Analytical) as described in Sisma-Ventura and Rahav (2019). The detection limit (3 times the standard deviation of 10 measurements of low nutrient seawater), was 0.08 \(\mu\)mol L\(^{-1}\) for NO\(_2^+\)NO\(_3^-\) (NOx), 0.008 \(\mu\)mol L\(^{-1}\) for PO\(_4^{3-}\) and 0.05 \(\mu\)mol L\(^{-1}\) for Si(OH)\(_4\). Analysis reproducibility was determined using MOOS 3 (PO\(_4^{3-}\), NOx and Si(OH)\(_4\)), VKI 4.1 (NOx) and VKI 4.2 (PO\(_4^{3-}\) and Si(OH)\(_4\)) certified references materials (CRM). Results were accepted when measured CRM’s were within ±5% from the certified values.
2.4. Chlorophyll-\textit{a} and algal photosynthetic pigments markers

Seawater samples (500 mL) were concentrated on deck using a Whatman GF/F (~0.7 µm pore size) at low pressure (<150 mbar) for chlorophyll-\textit{a} (chl-a) analysis. The filters were placed in glass vials and frozen in the dark at -20 °C until analysis. Chl-\textit{a} pigment was extracted overnight in cold acetone (90%) in the dark and determined by the non-acidification method (Welschmeyer, 1994) using a Turner Designs (Trilogy) fluorometer. The chl-\textit{a} reads were then calibrated against the \textit{in situ} fluorimeter mounted on the rosette, using a linear regression equation \((n=19, r=0.95, p<0.001)\). For biomarker photosynthetic pigments analyses, 8 L of seawater were concentrated on GF/Fs, and kept frozen at -20 °C in aluminum foil until analysis. High-Performance Liquid Chromatography (HPLC) was used to identify and quantify the biomarker photosynthetic pigments concentrations using a 40 min Ethyl-acetate methanol gradient method (Jeffrey et al., 1997). Pigments were extracted in 90% acetone for 24 h in 4 °C. The extracts were filtered through a 0.45 µm Teflon syringe filter and transferred into glass HPLC vials. The extracts (100 µL) were analyzed using an Agilent 1220 HPLC system equipped with a diode array and fluorescence detectors. Selected pigment standards (DHI Labs) were used for verification of the spectra and retention times.

2.5. Pico/nano-phytoplankton and heterotrophic prokaryotic abundance

Samples (1.8 mL) were fixed with glutaraldehyde (final concentration 0.02% \textit{v:v}, Sigma-Aldrich G7651), frozen in liquid nitrogen, and later stored at -80 °C until analysis within a week. The abundance of autotrophic pico- and nano-eukaryotes, \textit{Synechococcus} and \textit{Prochlorococcus} and other heterotrophic prokaryotes (bacteria and archaea) was determined using an Attune® Acoustic Focusing Flow Cytometer (Applied Biosystems). Heterotrophic prokaryotes (hereafter refer to as heterotrophic bacteria, BA) were stained with SYBR Green (Applied Biosystems). Total phytoplankton and microbial biomass were calculated according to Houlbrèque et al. (2006). Phytoplankton and microbial doubling time estimates were calculated by dividing the integrated phytoplankton biomass by integrated primary and bacterial production, respectively (Kirchman, 2012).

2.6. Primary production (PP)
Triplicate water samples (50 mL) were spiked upon sampling with 5 μCi of NaH$^{14}$CO$_3$ (Perkin Elmer, specific activity 56 mCi mmol$^{-1}$) (Steemann-Nielsen, 1952). The samples were incubated for 24 h under in situ natural illumination and surface temperature in a flow-through tank on deck covered with a light screening mesh. The incubations were terminated by filtering the spiked seawater through GF/F filters (Whatman, 0.7 μm pore size) at low pressure (~50 mmHg). Measurements for the added activity and dark controls were also performed. The filters were placed overnight in 5 mL scintillation vials containing 50 μl of 32% hydrochloric acid to remove excess $^{14}$C, after which 5 mL of scintillation cocktail (Ultima-Gold) were added. Radioactivity was measured using a TRI-CARB 2100 TR (Packard) liquid scintillation counter.

Note that the rates considered here only account for the particulate PP and not the dissolved fraction, and therefore the total PP may be underestimated (by average ~20% in oligotrophic seas, Marañón et al. 2005). Yet, we surmise that if underestimation did occur, it was similar in all stations sampled. Moreover, it is to be noted that due to the relatively low number of depths sampled in each station (n=5-6), it is possible that some peaks in PP (e.g., at the subsurface) may have been overlooked, resulting in underestimation of the integrated values.

### 2.7. Bacterial production (BP)

Prokaryotic (bacteria and archaea) heterotrophic production (hereafter refer to as BP) was estimated using the $^3$H-leucine incorporation method (Perkin Elmer, specific activity 100 Ci mmol$^{-1}$). Three replicates (1.7 mL each) from each water depth were incubated in the dark (wrapped in aluminum foil) with ~10 nmol hot leucine L$^{-1}$ for 4 h (Rahav et al., 2019). Control treatments in which surface water was immediately added with 100 μl of 100% trichloroacetic acid (TCA, 4 °C) along with $^3$H-leucine were also carried in triplicates. The incubations were terminated with TCA and were later processed following the microcentrifugation technique (Smith et al., 1992) and added with 1 ml of scintillation cocktail (Ultima-Gold). The samples were counted using a TRI-CARB 2100 TR (Packard) liquid scintillation counter. A conversion factor of 1.5 kg C mol$^{-1}$ per every mole leucine incorporated was used (Simon et al., 1989).

### 2.8. Zooplankton biomass
Zooplankton samples were sieved through a 100-µm mesh and halved into two subsamples using a plankton sample splitting box (Motoda, 1959). One subsample was kept at -20 °C for biomass analysis and the second subsample was preserved in 99.8% ethanol for molecular analysis (Harris et al., 2000). In the lab, the collected samples were thawed and filtered using pre-combusted GF/C filters and weighed after drying in 60 °C for 24 h to obtain dry weight (DW), and after 4 hours in 500 °C to measure ash weight and obtain carbon content as ash free dry weight (AFDW).

The grazing impact of zooplankton on phytoplankton was calculated as the relative portion of zooplankton carbon biomass from the total pico/nanophytoplankton biomass.

2.9. Zooplankton carbon and nutrient demand estimates

Zooplankton carbon demand (ZCD in mg C m⁻³ d⁻¹) was calculated based on measured biomass and growth rate estimates (following the cross-Mediterranean estimates in Feliú et al., 2020):

\[ ZCD = C_{zooplankton} \times F_R \]

Where, \( C_{zooplankton} \) is the carbon concentration of zooplankton (in mg C m⁻³) and \( F_R \) is the food ratio, defined as the amount of food consumed per unit of biomass per day (d⁻¹), calculated as:

\[ F_R = \frac{g_Z + r}{A} \]

Where, \( g_Z \) is the growth rate, \( r \) is the weight specific respiration and \( A \) is assimilation efficiency. \( r \) and \( A \) were set to 0.16 d⁻¹ following Alcaraz et al. (2007) and 0.7 following Nival et al. (1975). \( g_Z \) was calculated following Zhou et al. (2010):

\[ g_Z(C_{zooplankton}, T, Chl. a) = 0.033 \left( \frac{Chl. a}{Chl. a + 205e^{-0.125T}} \right) e^{0.097W_{ZOOP} - 0.06} \]

Where, \( T \) is seawater temperature (average value for 0-300 m: background 18.8 °C, cyclone 17.8 °C, anti-cyclone 20.0 °C), chl-a is food availability (mg C m⁻³) estimated from the integrated chl-a values. \( W_{ZOOP} \) is the average carbon concentration per zooplankter, set to 0.01072 mg C ind⁻¹ based on data collected from the background station in 2019-2020 (Guy-Haim, unpublished data). Phytoplankton was considered as food following Calbet et
al. (1996). ZCD was compared to the phytoplankton stock and to primary production to estimate the potential clearance of phytoplankton by zooplankton.

N and P excretion and oxygen consumption rates for an average zooplankter with weight $W_{ZOO}$ were estimated using the multiple regression model by Ikeda, (1985) based on carbon weight and temperature:

$$\ln Y = a_0 + a_1 \ln W_{zoo} + a_2 T$$

Where $Y$ represents N or P excretion or oxygen uptake. $a_0$, $a_1$, and $a_2$ are constants specific to each metabolic process (respiration, ammonia and phosphate excretion). Total N and P excretion were obtained by multiplying the obtained rate with the zooplankton biomass measured at each station. Zooplankton's contribution to nutrient regeneration (in %) was estimated by comparison to primary production converted to N and P requirements. To this end, we used C:N:P ratios different than the ‘typical’ Redfield 106:16:1 stoichiometry as previously reported in the ultra-oligotrophic Levantine basin water (Pujo-Pay et al., 2011). Where, the POC:PN is 5.4:1 (instead of ~6.6:1) and POC:PP is 116:1 (instead of 106:1). Respiration was converted to respiratory carbon lost assuming a respiratory quotient of 0.97 following Ikeda et al. (2000) and used as a carbon requirement for zooplankton metabolism.

2.10. Molecular diversity of microbial and zooplankton communities

Seawater (8 L) was filtered using a peristaltic pump onto Supor membrane filters (0.2 μm, 47 mm, PALL, USA) and placed immediately in PowerWater DNA bead tubes (Qiagen, USA), flash-frozen in liquid nitrogen and preserved at -20 °C (n=1 per depth except in selected samples where n=2). DNA was extracted with the DNeasy PowerWater Kit (Qiagen, USA), following the standard protocol including an extra heating step at 65 °C for 10 min as recommended by the manufacturer for samples containing algae. Ethanol-preserved zooplankton samples were sieved using a 100-μm Nitex sieve, washed with distilled water to remove ethanol residuals, and homogenized by vigorous vortex and pipetting. Genomic DNA was extracted using DNeasy Blood and Tissue Kit (Qiagen, USA) following the manufacturer's instructions.
DNA was amplified with the following primer sets amended with CS1/CS2 tags: i) The V4 region of the 16S rRNA gene (ca. 300 bp), 515Fc/806Rc, (Apprill et al., 2015; Parada et al., 2016); ii) the 18S rRNA gene (200-500 bp); 1391F, EukBr, (Amaral-Zettler et al., 2009), and iii) the mitochondrial cytochrome c oxidase I (COI) gene (ca. 300 bp), mlCOIintF, jgHCO2198. Library preparation from the PCR products and sequencing of 2x250 bp Illumina MiSeq reads was performed by HyLabs (Israel). The COI and 18S rRNA gene amplicon reads were submitted to NCBI Sequence Read Archive BioProject PRJNA667077.

2.11. Bioinformatic analyses of marker gene amplicons

Demultiplexed paired-end reads were processed in QIIME2 V2020.6 environment (Bolyen et al., 2019). Reads were truncated based on quality plots, checked for chimeras, merged and grouped into amplicon sequence variants (ASVs) with DADA2 (Callahan et al., 2016), as implemented in QIIME2. The 16S and 18S rRNA amplicons were classified with scikit-learn classifier that was trained on the Silva 138 database or BLAST against the Silva 138 database (0.9 minimum identity cutoff, performed best for the analyses of 18S gene amplicons of microbial zooplankton). COI amplicons were classified with BLAST (0.9 minimum identity cutoff) against the merged NCBI/BOLD database (Heller et al., 2018), which was transformed into QIIME2 format. Downstream statistical analyses, calculation of alpha diversity indices (the richness estimator ACE - Abundance-based Coverage Estimator, and the biodiversity estimators Shannon and Simpson), beta diversity (non-metric multidimensional scaling, NMDS, based on the Bray-Curtis dissimilarity) and plotting were performed in R (R Core Team, 2018) using packages phyloseq (McMurdie and Holmes, 2013), ampvis2 (Andersen et al., 2018) and ggplot2 (Wickham, 2011). Mitochondrial and chloroplast sequences were removed from the 16S rRNA amplicon dataset, the relative abundance of microbial eukaryotes was estimated following the removal of metazoan 18S rRNA sequences.

2.12. Statistical analyses

Nutrients, pico-phytoplankton, heterotrophic bacteria, as well as primary and bacterial production were vertically integrated using the trapezoidal rule, and compared between sampling locations (‘background’, ‘anti-cyclonic eddy’ and ‘cyclonic eddy’) using a one-
way ANOVA and a Fisher LSD means comparison test (α=0.05). Statistically significant differences (p<0.05) were labeled with different letters. DESeq2 (Love et al., 2014) was used to evaluate the differential abundance of bacterioplankton ASVs at the DCM. Note that the limited number of samples collected in each hydrologic discontinuity per depth (n=1-2), contrary to integrated calculations which pool 4-6 measurements from the upper 180 m, restricted our ability to run additional statistical comparisons between locations. We discuss these caveats below and also compare our findings to other relevant studies from the Mediterranean Sea (i.e., BOUM and ISRALEV campaigns) and elsewhere (e.g., the Eastern Indian Ocean, Waite et al. 2007), as well as compare our nutrients and chl-a profiles to a parallel cruise held at the same time of our study nearby (Figure S1).

3 Results

The AMEDA algorithm shows a chain of cyclonic and anti-cyclonic eddies at the SEMS (Figure 1A). The stations were selected to sample the cores of the southern cyclonic and anti-cyclonic eddies offshore the Israeli coast, as well as background stations. The anti-cyclone, later identified in the DYNED atlas as anti-cyclone #12683, was created from a meander of the along-shore current in the southeastern corner of the basin in early August 2018, just 62 days prior to the cruise. It mixed warm water from the eastern sea margin (Figure S2A). The cyclonic eddy was created in early February 2018, 246 days before the cruise. Later, when the DYNED atlas was extended to include 2018, it was identified as cyclonic eddy #11988 that was created more than a year earlier, mid-September 2017 (Figure S2). It was split from cyclone #11310 located south of Cyprus and migrated to the easternmost SEMS. Profiles of Argo floats (#6903221 and #6903222) localized within cyclone #11310 showed that it brought denser, colder and saltier water upwelled on the southern Cyprus coast (Figure S2A). At the time it was sampled it is characterized as a cold-core cyclone, colder than its surrounding waters (Figure S2B).

The sea surface temperature (SST) in the anti-cyclonic eddy and background stations was the warmest (~28 °C), while a lower temperature was recorded in the cyclonic eddy (~27 °C) (Figure 1B; Figure S3). Further, down to 550 m the highest water temperatures were recorded in the anti-cyclonic eddy (a positive anomaly compared to the background), and the coldest temperatures were recorded in the cyclonic eddy (a negative
anomaly). From ~550 m to 1000 m depth the water temperature in all sampling stations was the same and constant (~14 °C) (Figure S3). Surface salinity ranged from 39.7 to 39.8 psu and decreased to 38.8 psu at 550 m in all sampling sites (Figure 1B, Figure S3). The concurrent potential density anomaly derived from a detailed glider mission that occurred the following week to our cruise shows that the sampling stations were within the cores of the two distinct hydrologic discontinuities (Figure 1C). The Levantine Intermediate Water (LIW), characterized by high salinity and relatively warm temperatures, was evident at ~70 m in the up-welling cyclonic eddy, ~130 m in the background station, and ~170 m at the down-welling anti-cyclonic site (Figure 1B). This means that at the core of the cyclone, the LIW mass was uplifted to a relatively narrow layer (50-80 m; core at 75m) while in the core of anti-cyclone the LIW was much wider and deeper (80-240 m; core 175 m) due to convergence of currents (Figure S3).

NO$_2^-$+NO$_3^-$ (NOx) and orthophosphate (PO$_4^{3-}$) concentrations were close to, or below, the detection limit of conventional analytical methods at all stations in the upper 100 m, while Si(OH)$_4$ levels were always above the detection limit (Figure 2A-C, Table S1). Nevertheless, marked differences were observed in the integrated nutrient values between sites at the photic layer (0-180 m), with 13-fold higher NOx, 2.5-fold higher PO$_4^{3-}$ and 1.5-fold higher Si(OH)$_4$ in the cyclonic eddy compared with the anti-cyclone (Table 1). Integrated N:P ratios at the background and anti-cyclone stations were lower than the Redfield ratio (15:1 and 9:1, respectively), whereas at the cyclone N:P ratio was higher (~48:1) (Table 1). From 180 m and down to the nutricline shoulder (~400 m), all nutrient levels gradually increased. Where NOx, PO$_4^{3-}$ and Si(OH)$_4$ were higher by 45%, 90% and 100% in the cyclonic eddy than the anti-cyclonic eddy, respectively (Figure 2A-C, Table S1).
Figure 1 – Altimetry map with eddies detected by the AMEDA algorithm created on the morning of the cruise (October 9, 2018), sampling stations (yellow marks) and a glider cruise-track (green dots) (A), temperature-salinity (T-S) diagram of the stations sampled (B), and the potential density anomaly derived from a glider mission (292 quasi-vertical profiles) held a few days after the cruise (October 13-31, 2018) (C). Contours on the density map show the corresponding isohalines.
Figure 2 – Vertical profile of NOx (A), PO$_4^{3-}$ (B) and Si(OH)$_4$ (C) in cyclonic (blue triangle) and anti-cyclonic (red square) eddies and an uninfluenced background station (white circle) in the southeastern Mediterranean Sea during October 2018.

Following the elevated nutrient levels, integrated chl-a was highest at the cyclonic eddy and background stations (20.0-21.3 mg m$^{-2}$), and lowest at the center of the ultra-oligotrophic anti-cyclonic eddy (17.9 mg m$^{-2}$) (Tables 1, S1). The deep chlorophyll maximum (DCM) spread from 90-120 m in the cyclonic eddy, while a smaller DCM shoulder was observed in the anti-cyclonic eddy (~90-120 m) and at the background (~120-130 m) stations (Figure 3A). Nonetheless, the cyclone had the highest chl-a concentration.
among all stations (0.31 µg L$^{-1}$) while the DCM in the anti-cyclonic eddy had a weaker Chl-a signal (0.18 µg L$^{-1}$) (Figure 3A, Table S1). *Synechococcus* was mostly found in the surface water of all stations, whereas *Prochlorococcus* occupied the DCM depths (Figure 3B, C). The highest cell abundance of these cyanobacteria was found at the background station (69x10$^{10}$ *Synechococcus* cells m$^{-2}$) and in the anti-cyclone (270x10$^{10}$ *Prochlorococcus* cells m$^{-2}$), while the lowest abundances were found in the cyclone (~27x10$^{10}$ *Synechococcus* cells m$^{-2}$ and ~160x10$^{10}$ *Prochlorococcus* cells m$^{-2}$) (Tables 1, S1). Cyanobacterial read abundance based on amplicon sequencing supported these findings (Figure 4). The dominant bacterioplankton lineages in the photic zone included SAR86, Flavobacteriales, Puniceispirillales, Rhodospirillales, SAR11 (clade Ia) and others (Figures 4, S4). The abundance of pico- and nano-eukaryotic phytoplankton was higher at the cyclonic station (13.5x10$^{10}$ cells m$^{-2}$) than the other stations sampled (~5.5x10$^{10}$ cells m$^{-2}$) (Tables 1, S1). Picoeukaryotes were mostly found in the surface water (top 50 m) and nanoeukaryotes were mostly found at the DCM depth (Figure 3D, E). Correspondingly, total pico-phytoplankton biomass was highest in the cyclonic eddy (597 mg C m$^{-2}$), which is 1.6-1.7-fold higher than at the background or anti-cyclonic stations (Tables 1, S1). 18S rRNA amplicon analyses indicated that at the photic depths mainly non-diatom microbial eukaryotes were dominant, such as dinoflagellates, Prymnesiophyceae and Ochrophyta (Figures 5, S5). Overall, the pico- and nano-eukaryotic populations were more diverse in the photic zone than in the deep waters, yet no major differences in alpha diversity parameters were observed between the stations (Figure S6).

Algal pigment analysis at the cyclone showed that the photosynthetic auxiliary pigments were mostly comprised of fucoxanthin (109 ng L$^{-1}$) - a pigment marker of diatoms, chrysophytes and some prymnesiophytes, and zeaxanthin (74 ng L$^{-1}$) - a pigment marker for green algae and cyanobacteria (Figure S7). At the anti-cyclonic eddy, fucoxanthin was also detected at the DCM, however, its concentration was lower by ~40% (~65 ng L$^{-1}$) while zeaxanthin concentration was slightly lower (~64 ng L$^{-1}$) (Figure S7). As very few diatoms were detected by the 18S rRNA amplicon analysis, we surmise that the presence of fucoxanthin was most likely attributed to prymnesiophytes. Although the most considered diagnostic marker for prymnesiophytes is 19-hexanoyloxyfucoxanthin,
previous studies showed that fucoxanthin can also be used as their marker in absence of 19-hexanoyloxyfucoxanthin signals (Ansotegui et al., 2003).
**Figure 3** – Vertical profile of chlorophyll $a$ (A), *Synechococcus* (B), *Prochlorococcus* (C), pico-eukaryotes (D) nano-eukaryotes (E) and primary production rate (F) at the photic layer of cyclonic (blue triangle) and anti-cyclonic (red square) eddies and an uninfluenced background station (white circle) at the southeastern Mediterranean Sea during October 2018.

**Figure 4** – The relative abundance of 30 most-abundant bacterial and archaeal genera collected at cyclonic and anti-cyclonic eddies, and an uninfluenced background station at the southeastern Mediterranean Sea during October 2018, as estimated by read abundance. Results of replicate casts in anti-cyclone and uninfluenced background (H05) stations are shown in columns with identical depths.
Figure 5 – The relative abundance of 20 most-abundant unicellular eukaryotic lineages (phylum level), collected at cyclonic and anti-cyclonic eddies, and at an uninfluenced background station (H05) at the southeastern Mediterranean Sea during October 2018, as estimated by read abundance. Results of replicate casts in anti-cyclone and control H05 stations are shown.

Following the higher nutrients levels and pico-phytoplankton biomass, PP was highest in the cyclone (191 mg C m\(^{-2}\) d\(^{-1}\)) and significantly decreased by 50-80% at the background (81 mg C m\(^{-2}\) d\(^{-1}\)) and anti-cyclone (36 mg C m\(^{-2}\) d\(^{-1}\)) stations (Tables 1, S1). The highest PP rates were found in the surface water of all stations (~0.8-2.0 µg C L\(^{-1}\) d\(^{-1}\)) and decreased with depth throughout the photic layer (Figure 3F). The differences in the vertical distribution of chl-\(a\) and PP were also evident in the assimilation number of phytoplankton, which signifies autotrophic specific activity (PP per chl-\(a\)). The assimilation number was highest at the cyclone (10 g C g Chl-\(a\)\(^{-1}\) d\(^{-1}\)) and lower by 60-80% in the anti-cyclone and background stations (2-4 g C g Chl-\(a\)\(^{-1}\) d\(^{-1}\)) (Tables 1, S1).
Integrated doubling times of pico/nano-phytoplankton was highest at the anti-cyclone (9.7 days) and lowest in the cyclone (3.1 days) (Table 1).

Total BA was higher by 1-2 orders of magnitude than the pico-phytoplankton abundance (Figure 6A, Table S1). The highest BA was measured at the anti-cyclone (2125x10^{10} cells m^{-2}) followed by the cyclonic eddy (2072x10^{10} cells m^{-2}) and background (1459x10^{10} cells m^{-2}) stations (Table 1). Contrary to the BA or biomass, BP was significantly higher at the cyclone (214 mg C m^{-2} d^{-1}) compared to the anti-cyclone and background stations (82-85 mg C m^{-2} d^{-1}) (Table 1). A similar trend was measured in heterotrophic bacteria cell-specific activity (BP/BA), where the most productive cells were found at the cyclone (10 fg C cell^{-1} d^{-1}), while the least productive cells were found at the anti-cyclone (4 fg C cell^{-1} d^{-1}) (Tables 1, S1). Overall, BP was homogeneously distributed throughout the photic layer in all stations (~0.2-0.9 µg C L^{-1} d^{-1}), except the cyclonic eddy where the rates were relatively high in the upper 100 m (~0.8-2.4 µg C L^{-1} d^{-1}) (Figure 6B). At 180 m, BP rates were similar at all stations (~0.1 µg C L^{-1} d^{-1}) (Figure 6B). The resulting BP/PP ratio was overall similar outside the cyclone; ~1, and was twofold higher inside it (Table 1). In accordance with the high BP, the integrated doubling time of heterotrophic bacteria was highest at the anti-cyclone (3.5 days) and lowest at the cyclone (1.4 days) (Table 1).

The slope of the log-log linear regressions for BA and BP obtained in the cyclonic eddy was 0.24 (R^2=0.60), while in the anti-cyclonic eddy the slope was more than twice as high; 0.52 (R^2=0.79) (P=0.03, Analysis of the Covariance [ANCOVA], Andrade & Estévez-Pérez 2014).
Figure 6 – Vertical profile of heterotrophic bacterial abundance (A) and bacterial production rates (B) at the photic layer of cyclonic (blue triangle) and anti-cyclonic (red square) eddies and an uninfluenced background station (white circle) at the southeastern Mediterranean Sea during October 2018.

In accordance with the high PP and BP, total zooplankton biomass in the upper 300 m was an order of magnitude higher in the cyclonic eddy (3045 mg DW m$^{-2}$, 1337 mg C m$^{-2}$) compared with the anti-cyclonic (303 mg DW m$^{-2}$, 133 mg C m$^{-2}$) or background (360 mg DW m$^{-2}$, 112 mg C m$^{-2}$) stations (Tables 1, S1). Zooplankton grazing impact on phytoplankton stock estimates shows that meso-zooplankton consumed 30-38% of the daily phytoplankton stock in the anti-cyclone and background stations and 224% in the cyclone (Table 1). Similarly to zooplankton biomass, the estimated zooplankton carbon demand (ZCD) was highest in the cyclonic eddy (∼388 mg C m$^{-2}$ d$^{-1}$) and decreased by an order of magnitude in the anti-cyclonic eddy (∼42 mg C m$^{-2}$ d$^{-1}$) and the background (∼34 mg C m$^{-2}$ d$^{-1}$) stations (Tables 1, S1). Considering phytoplankton as the major food source, zooplankton potentially consumed 203% of PP in the cyclonic eddy, 116% in the anti-cyclonic eddy, and only 42% in the background station (Tables 1, S1). Zooplankton respiration rates were 9-11-fold larger in the cyclone (∼166 mg C m$^{-2}$ d$^{-1}$) than in the anti-cyclone and background stations (∼15-19 mg C m$^{-2}$ d$^{-1}$), corresponding to 87% vs. 18-53% of the integrated PP (Tables 1, S1). The estimated contribution of zooplankton to nitrogen
regeneration by excretion of ammonium was 9-11 fold greater in the cyclone (25 mg N-NH\textsubscript{4} m\textsuperscript{2} d\textsuperscript{-1}) than in the anti-cyclone or the background stations (~2-3 mg N-NH\textsubscript{4} m\textsuperscript{2} d\textsuperscript{-1}), corresponding to 61% vs. 13-37% of the integrated PP (based on a C:N 5.4:1 ratio, Pujo-Pay et al., 2011) for the Levantine Basin water (Tables 1, S1). The estimated contribution of zooplankton to phosphorus (as orthophosphate) by excretion was an order of magnitude greater in the cyclone (3.6 mg P-PO\textsubscript{4} m\textsuperscript{2} d\textsuperscript{-1}) than in the anti-cyclone and background stations (0.3-0.4 mg P-PO\textsubscript{4} m\textsuperscript{2} d\textsuperscript{-1}), corresponding to 85% vs. 17-50% of the integrated PP (based on a C:P 116:1 ratio, Pujo-Pay et al., 2011) (Tables 1, S1).

Zooplankton alpha diversity estimated based on the COI and 18S rDNA genes read abundance as well as by cell abundance (i.e., microscopic identification) was highest in the cyclone and background stations, and lowest in the anti-cyclone (Figure 7). COI and 18S ASV richness (ACE index) were lowest in the anti-cyclone (29 and 81, respectively), and 60% (18S) to 250% (COI) larger in the cyclone and background stations (Figure 7). The lowest zooplankton biodiversity (Shannon and Simpson indices) was found in the anti-cyclone, using both genes (Figure 7). These findings were confirmed with rarefaction curves (Figures S8, S9).
Figure 7 – Zooplankton alpha diversity indices (ACE ±SE, Shannon, Simpson) based on 18S (green) and COI (yellow) amplicon sequencing in >100-µm samples collected from the upper 300 m of cyclonic and anti-cyclonic eddies, and at an uninfluenced background station at the southeastern Mediterranean Sea during October 2018.

Classification to species level was successful in 211 out of 221 COI ASVs and in only 55 out of 830 18S ASVs, 200 of which were classified to an order level. The three stations differed in the zooplankton relative richness (i.e., number of ASVs per taxonomical functional group) (Figure 8). Overall, in all stations, copepods (Hexanauplia) were the most diverse group, nevertheless, copepod richness was 7-fold larger in the cyclone vs. the anti-cyclone. Ostracods and hydrozoans (mainly siphonophores) had higher diversity in the background station than in the other stations. Chaetognaths, branchiopods (cladocerans), planktonic decapods and amphipods, had similar richness levels in the cyclonic eddy and background stations, however, they were completely absent in the anti-cyclone. In contrast, a higher richness of gastropods (mainly pteropods) was found in the anti-cyclone compared to the cyclone and background stations. Although the majority of the taxonomic groups were better represented by COI classification, one group – Polychaeta – was better represented in the 18S rRNA (2 versus 12 ASVs), as 18S is more often used to obtain resolved phylogenies in polychaetes (Colgan et al., 2006). Based on the 18S rRNA gene ASVs, the highest richness of polychaetes was found in the cyclone (6 ASVss) and background (5 ASVs) stations, whereas only 2 ASVs were found in the anti-cyclone.
Figure 8 – Zooplankton species richness based on COI amplicon sequences (classified using BOLD/NCBI-based database) in >100-µm samples collected from the upper 300 m of cyclonic and anti-cyclonic eddies, and at an uninfluenced background station at the southeastern Mediterranean Sea during October 2018. *Polychaeta richness was obtained from rRNA 18S amplicon sequences.
Table 1 – Chemical and biological integrated values at the upper 180 m (except zooplankton where 0-300 m is presented) measured in the different sampling sites. The maximal values for each variable are highlighted in bold.

**4 Discussion**

Seasonality is the primary driver affecting water column characteristics in the SEMS, where external inputs of nutrients such as from the atmosphere (Herut et al., 2002, 2005; Ridame et al., 2011) or large rivers (Krom et al., 2014; Ludwig et al., 2009) are limited in space and time. Thus, the one-dimensional processes of summer stratification and winter mixing determine, to a large extent, the nutrient availability in the photic layer (<180 m), subsequently affecting phytoplankton population dynamics and activity (van Ruth et al., 2020). However, horizontal variability plays an important role. Turbulent mesoscale eddies are a prominent part of the circulation in the SEMS (Mkhinini et al., 2014). Such features have lifetimes of a few months to a year (Mkhinini et al., 2014), affecting the availability of the nutrients to phytoplankton and bacteria in the photic layer (Rahav et al., 2013; Vaillancourt et al., 2003), and thus to higher trophic levels (Dolan et al., 2002; Siokou-Frangou, 2004). The degree to which an eddy affects the community depends on the eddy’s size, age, the source of the water ‘trapped’ within it, and the interaction with wind and land (Gaube et al., 2014; Huggett, 2014; Landry et al., 2008; Strzelecki et al., 2007). Our results demonstrate that upwelling within the cyclone injected deeper water nutrients into the quasi-permanent eddy, thus fertilizing the planktonic population.

The effect of hydrodynamic structures on planktonic microbial distribution has been studied previously in the SEMS. However, these studies focused on long-lived anticyclonic eddies such as the Cyprus/Shikmona Eddy (>6 months, Christaki et al., 2011; Rahav et al., 2013; Thingstad et al., 2005). There is a strong asymmetry in eddy's lifetime, which on average is far shorter for cyclones than anti-cyclones. This asymmetry is enhanced in the SEMS where the cyclone lifetime distribution is very similar to the rest of the Mediterranean Sea, yet the anti-cyclones live longer (Mkhinini et al., 2014). It makes the comparison of cyclones and anti-cyclones more challenging in the SEMS as they are...
not circulating (and thus isolated) for the same time. We sampled a recent anti-cyclone (#12683, two months old) and a more ‘mature’ cyclone (#11988, over a year old), which is not the usual scenario in the SEMS. The short-lived anti-cyclone and the background station indeed have similar characteristics. We expect long-lived anticyclones to be even more oligotrophic, making their influence more prominent, as discussed below.

4.1. Pico-phytoplankton dynamics and primary production in anti-cyclonic and cyclonic waters

Our results show that nutrient availability affected the pico-phytoplankton dynamics in the SEMS. The low pico-eukaryotes biomass and the low N:P in the anti-cyclonic eddy (~9:1) suggest N limitation for these autotrophs under extreme oligotrophic conditions (Table 1). Contrary, the high N:P ratio (~48:1) and the relatively low cyanobacterial biomass in the cyclonic eddy suggest that *Synechococcus* and *Prochlorococcus* are P-limited. These results are similar to a previous study from the SEMS showing that NOx concentrations at the Rhodes Gyre (up-welling) were 5-fold higher than in the Cyprus Eddy (down-welling), while PO$_4^{3-}$ remained similarly low for the two locations (Rahav et al., 2013). These variations result in significant differences in the NOx:PO$_4^{3-}$ ratio of the two systems; Rhodes Gyre (~ 50:1) and Cyprus Eddy (~10:1), implying similar nutrient limitations as discussed above. Stoichiometric N:P Redfield ratio alone, however, cannot fully explain which nutrients limit the microbial plankton diversity. Some phytoplankton species have nutritional requirements different than N:P=16, and there are several ‘non-Redfield’ processes in the aquatic ecosystem, which may alter the N:P ratio, regardless of any nutrient limitation (Arrigo, 2005; Geider and La Roche, 2002; Moore et al., 2013).

The integrated chl-a content at the background, the anti-cyclone, and the cyclonic stations exhibited overall low variability (~18-21 mg chl-a m$^{-2}$), yet the integrated primary production in the cyclone was ~5 times higher, resulting in a higher assimilation number. This high assimilation number indicates a better efficiency of carbon incorporation per chl-a unit and thus a better algal physiological state at the cyclone relative to that of other stations considered. This is likely owing to the higher nutrient availability (i.e., N and P) at the cyclone relative to the other more oligotrophic sites sampled (Table 1). It may also suggest different community compositions and cell sizes.
The overall low PP outside the cyclone (Figure 3F, Table 1) is in accordance with another low nutrient low chl-a (LNLC) systems (Falkowski et al., 2003; Lomas et al., 2013) and aligned with the threshold limit of oligotrophic oceans; < 100 mg C m^{-2} d^{-1} (Koblentz-Mishke et al., 1970). Low PP may be driven by several factors such as nutrient availability (Kress et al., 2005), light levels (Dishon et al., 2012; Sathyendranath and Platt, 2007; Stambler, 2012), viral infection (Guixa-Boixereu et al., 1999b, 1999a), and top-down grazing by zooplankton (Griffin and Rippingale, 2001; Olli et al., 2007; Rakhesh et al., 2008). We surmise that the overall low PP was mainly driven by the N and P standing stocks in the photic layer, including the cyclone (Table 1). This is because light levels were similar in all stations and therefore unlikely to affect the daily PP rates between sites. Moreover, viral-induced mortality was shown to be less important than mortality due to grazing by protists in the SEMS as has been shown in unamended eastern Mediterranean surface water in mesocosms (Tsiola et al., 2017). Contrary, the grazing impact on phytoplankton was significantly higher in the cyclone compared to the other more oligotrophic sites (~200% vs. ~40-100%, respectively, Table 1). Despite the potentially high grazing pressure in the cyclone, higher phytoplankton biomass and PP were measured in this upwelling site. These differences between sites are likely attributed to the different phytoplankton growth rates, as phytoplankton's doubling time at the cyclone was ~3 days, while 5-10 days was estimated in the anti-cyclone and background stations. These doubling time estimates are in the same order as reported in other marine environments, ranging from ~1 day (reviewed in Laws 2013) to 10 days (Dyhrman et al., 2012), and are in agreement with recent estimates from the central and western Mediterranean Sea (Marañón et al., 2021). We note that doubling time estimates have many caveats, mostly because some phytoplankton or bacteria comprise an unknown fraction of the POC pool, and it is a methodological challenge to separate them from all other particles in the water (Laws, 2013). Moreover, grazing impact on PP calculated from mesozooplankton biomass alone may lead to an overestimation of the top-down impact on autotrophic microbial populations (Feliú et al., 2020). Therefore, it is likely that we overestimated the grazing impacts on PP, which exceeded 100% in the cyclone (Table 1). Some mesozooplankton species can simultaneously graze both phytoplankton and heterotrophic prey (i.e., heterotrophic dinoflagellates and ciliates, Dolan et al., 2002; Sherr and Sherr, 2007). Such a
“multivorous” feeding strategy may explain the >100% mesozooplankton grazing impact on PP in the cyclone (Gasol et al., 1997). Moreover, the high estimated contribution of N and P by zooplankton to the PP by excretion at the cyclone (61-85%, Table 1) suggests rapid nutrient recycling that fuels the high production at this site. Contrary, in the anti-cyclone and background stations a lower N and P excretion by zooplankton was estimated (Table 1), therefore support only a minor part of the PP.

4.2 Heterotrophic bacterial abundance and production in anti-cyclonic and cyclonic waters of the SEMS

Prokaryotic microorganisms are important components of the marine food web, playing a pivotal role in many biogeochemical cycles (e.g., Kirchman, 2012). In warm and oligotrophic environments, such as the SEMS, heterotrophic bacterial metabolism is often equal or even higher than autotrophic activity (Luna et al., 2012; Pulido-Villena et al., 2012; Rahav et al., 2019). Our results show that while the abundance of heterotrophs was overall similar in the cyclone and anti-cyclone, their cell-specific activity was nearly threefold higher in the nutrient-richer cyclone (Table 1). Given that average bacteria contain 14 fg C cell⁻¹ (Gundersen et al., 2002), our estimate of bacterial cell-specific activity suggests that heterotroph doubling time in the cyclone is ~2 faster than the less productive anticyclone and background stations (Table 1). The differences in cell-specific activity and corresponding doubling time between sites are likely supported by the supplement of limiting nutrients for heterotrophic bacteria. Previous studies showed that P and/or dissolved organic carbon (DOC) are the limiting factors for heterotrophic microbial activity in the SEMS (Pitta et al., 2017; Rahav et al., 2019, 2021). We hypothesize that in the cyclone heterotrophic bacteria are likely DOC rather than P-limited since the PO₄³⁻ concentrations at this location were ~3-fold higher than in the other locations (Table 1). The high mesozooplankton excretion in the cyclone may add DOC and inorganic nutrients, which could partly fulfill the metabolic requirements of the heterotrophic bacteria. Contrary, in the background and anti-cyclone stations heterotrophic prokaryotes were likely P limited, as previously demonstrated in onboard microcosm experiments (Rahav et al., 2021; Zohary et al., 2005) and using indirect N:P stoichiometric mass balance calculations (Krom et al., 2005).
The ratio between BP and PP is commonly used as an indicator for the carbon flux derived from photosynthesis channeled through the microbial heterotrophic food web (Cole et al., 1988). The higher the ratio, the lower the amount of carbon available for export through herbivorous food webs. Here, the BP rates were two times higher than PP in the LNLC anti-cyclone (Table 1), suggesting that microbial heterotrophs outcompeted phytoplankton for most of the available nutrients. The equal BP and PP in the background and the cyclone stations demonstrate an imbalanced microbial metabolism, highlighting the importance of heterotrophy in SEMS. Previous studies from the anti-cyclonic Cyprus Eddy (Thingstad et al., 2005) and throughout the Mediterranean Sea (Rahav et al., 2021) suggested that heterotrophic bacteria may outcompete phytoplankton or diazotrophs for PO$_4^{3-}$. This is in contrast to most oceanic regimes, in which BP:PP<1 at the photic layer (e.g., Lomas et al., 2013). We note that some studies suggest that a net heterotrophy in a given system is biased due to an underestimate of PP and/or an overestimate of respiration rate. We currently cannot refute nor reinforce this debate, as we did not measure respiration rates. Community respiration rate measurements, although technically challenging, are needed, especially in light of the future climate-change predictions stating the oceans will become more heterotrophic (Duarte et al., 2013).

The slope of the log-log linear regressions for BA (as a biomass) and BP (a proxy of resource availability) suggest that bacterioplankton were bottom-up regulated in the anti-cyclone and top-down regulated in the cyclone (Billen et al., 1990; Ducklow, 1992; Pulido-Villena et al., 2012), in agreement with the estimated growth rates calculated above (sub-section 4.2). These values concur with other studies from the Mediterranean offshore water where the log-log regression of BA vs. BP is usually ~0.40 (Ducklow, 1992; Mével et al., 2008; Zohary and Robarts, 1998). Top-down and bottom-up factors are constantly changing in oligotrophic environments where organic matter flux is sporadic rather than continuous and where PP and grazing pressure may vary greatly on a temporal scale (Pulido-Villena et al., 2012). Understanding the feedback mechanisms controlling heterotrophic bacterial abundance and production in LNLC environments is of great ecological importance, especially in areas such as the Mediterranean Sea where the water column is rapidly warming and thus heterotrophic metabolism is likely to be more dominant (Luna et al., 2012; Rahav et al., 2019).
4.3 Zooplankton biomass, estimated carbon and nutrient demand

Our results show that zooplankton biomass was one order of magnitude higher in the more productive cyclone than in the anti-cyclone and background stations. This is in line with previous studies (Goldthwait and Steinberg, 2008; Landry et al., 2008b; Liu et al., 2020; Riandey et al., 2005; including the Levantine Basin Mazzocchi et al., 1997; Pancucci-Papadopoulou et al., 1992), which showed that higher productivity (either as PP or chl-a levels) in cyclonic eddies leads to higher zooplankton biomass. Zooplankton biomass reflected the higher PP at the photic layer, rather than the standing stock of the primary producers, possibly due to the higher estimated grazing impact on phytoplankton stock in the cyclone vs. the anti-cyclone and background stations (Table 1). A recent study from the central and western Mediterranean Sea demonstrated that the nutrient diffusive fluxes across the nutricline contribute only a minor fraction of the phytoplankton N and P requirements in the deep photic layer (Marañón et al., 2021). This suggests that generally phytoplankton depend on regenerated nutrients for growth rather than their supply from the nutricline in the SEMS.

The estimated integrated contribution of zooplankton to carbon turnover and nutrient remineralization was markedly higher in the cyclone than in the anti-cyclone and background stations. Since the dietary needs of some zooplanktonic species diverge from the Redfield ratio (Arrigo, 2005; Geider and La Roche, 2002; Moore et al., 2013), our estimates are based on the particulate C:N:P values reported from the Levantine basin water (Pujo-Pay et al., 2011). The contribution of PO$_4^{3-}$ by excretion of zooplankton to the estimated demand of phytoplankton was higher than their contribution of N (~85% vs ~60% respectively). The fact that there is a markedly high excess of N relative to P in the photic layer of the cyclone (Table 1), implies that the P was consumed not only by phytoplankton. This further supports the ‘orthophosphate bypass theory’ suggested by Thingstad et al., (2005) which showed that PO$_4^{3-}$ can be rapidly transferred through the microbial food web to copepods, bypassing the phytoplankton compartment, via luxury consumption mechanisms that shift the stoichiometric composition of copepod prey.

In addition to the higher PP rates, the higher zooplankton concentrations in the cyclone may also be attributed to lower temperatures, potentially providing a thermal refuge for different larvae as shown by model simulations (Limer et al., 2020). Such a
temporal or quasi-permanent shelter from detrimental environmental conditions can be especially important to the native biota in the rapidly warming Levantine Basin (Ozer et al., 2017). Furthermore, the warmer waters of anti-cyclonic eddies, arriving from the southeastern corner of the Levantine basin (as in our case, Figure S2), may carry thermophilic Indo-Pacific species, and facilitate their introduction and spread throughout the SEMS. The potential role of cyclonic eddies as thermal refugia for native species and anti-cyclonic eddies as introduction and dispersal vector for alien Indo-Pacific species should be investigated in future studies as cyclonic and anti-cyclonic features are likely to become more prominent in the future Mediterranean Sea (Siokou-Frangou et al., 2010).

4.4 Diversity of bacterioplankton and planktonic protists

Multivariate analyses of bacterioplankton diversity suggest that at the DCM and 180 m depths, the bacterioplankton community at the cyclone station differed from that of the respective depths at the anti-cyclone and background stations (Figure S10). These changes may be attributed to the depths of the nutricline, which vary between locations (Figure 2), and/or selective grazing pressure caused by different zooplankton species with different nutrition preferences (see discussion below). The microbial communities at the cyclone station were more similar to those of the deeper depths at the anti-cyclone and background stations. For example, the DCM community of the cyclone resembled the community at 180 m depth of the anti-cyclone (Figure S10). It has been shown that nutrient-poor anti-cyclonic gyres select for Prochlorococcus (Vaillancourt et al., 2003), and potentially for diazotrophs (Church et al., 2009; Fong et al., 2008; Rahav et al., 2013). Alongside the integrated cell counts (Table 1), diversity analyses suggest that Prochlorococcus is indeed most abundant at the anti-cyclone (~8% read abundance at the DCM), as opposed to ~5-6% at the control and cyclone’s DCM communities. We have, however, not identified cyanobacterial diazotrophs such as Trichodesmium and UCYN-A in any of our stations, in agreement with previous findings that showed uncoupling of PP and N₂ fixations in the SEMS (Rahav et al., 2013). Apart from Prochlorococcus, ASVs of heterotrophic/mixtrophic lineages, such as SAR324, Flavobacteriales, Rhodospirillales, Punicespirillales, Opitualae, SAR86, SAR11 were depleted at the cyclone’s DCM (DESeq2, adjusted p<0.05), implying a community-level shift driven by up-welling and
down-welling processes. The actual drivers of these shifts (e.g., water mass movement, temperature, nutrient availability, interactions with another biota including phage predation) remain to be elucidated.

High N:P ratios were suggested to have a large effect on the diversity of micro-eukaryotes (e.g., Cercozoa, Ciliophora and Dinoflagellata), while pico- and nanoeukaryotes (e.g., dinoflagellates, Bacillariophyta, Chlorophyta and Haptophyta) are more adapted to the P-poor (and thus high N:P) conditions due to their high surface to volume ratio (Kruk and Segura, 2012). In agreement with this notation, we found that the Oligotrichia ciliates (Ciliophora) comprised ~9% ASV read abundance in the cyclone DCM; opposed to <1% at the anti-cyclone/background stations. These ciliates can feed on algae (as well as bacteria) and retain ingested chloroplasts (McManus et al., 2018), and thus potentially contribute to PP. However, we also identified a high read abundance of Radiolaria (RAD A, Retaria) at the anti-cyclone’s DCM (~9%, Figure S5), indicating either that these organisms were indeed abundant, or suggesting that radiolarians that often carry multiple nuclei (Suzuki et al., 2009) may introduce noise to the marker gene diversity results.

The potentially toxic dinoflagellate *Karlodinium* was most abundant at the anti-cyclone’s DCM (2.1-2.6% of ASV reads) and least abundant at the cyclone station’s DCM (0.7% of ASV reads). A previous study suggested that the presence of this dinoflagellate may be related to P limitation, where it can switch from autotrophy to phagotrophy to take up nutrients from prey (Lin et al., 2016), providing it a competitive advantage. Indeed, the very low levels of PO$_4^{3-}$ in the DCM of the anti-cyclone (below detection limit), opposed to the cyclone’s DCM (~0.02 µmol Kg$^{-1}$), may explain the presence of this dinoflagellate and highlight that the different nutrient regimes may alter the diversity of protist communities in the SEMS.

Temperature is the main factor governing the distribution of planktonic protists in the SEMS (Santi et al., 2020). It is thus likely that the marked differences in the surface water temperature affect the diversity patterns of protists in warm and cold-core eddies. In the anti-cyclone, Syndiniales, which includes several known parasitic microbes (Guillou et al., 2008) were markedly enriched in surface waters (12 Syndiniales ASVs) relative to the other stations sampled. The relative abundance of these dominant parasites, which infect
and kill other protists, such as dinoflagellates, cercozoans and radiolarians, as well as metazoans (Clarke et al., 2019), positively correlates with temperature (Anderson and Harvey, 2020). This is likely because temperature accelerates their metabolic rates, increasing infectivity and dinospore production (Anderson and Harvey, 2020; Coats and Park, 2002).

4.5 Zooplankton diversity in anti-cyclonic vs. cyclonic waters at the SEMS

Cyclonic and anti-cyclonic eddies can entrain different zooplankton communities and biodiversity, distinctly different in their biogeographic origin from the adjacent waters (Hernández-León et al., 2001; Isla et al., 2004; Mackas et al., 2005; Pinca and Dallot, 1995; Riandey et al., 2005). In our study, we used meta-barcoding of mitochondrial (COI) and nuclear (18S) genes to assess the diversity of the mesozooplankton communities in the background, cyclone and anti-cyclone stations. We found that, although the background station had zooplankton biomass similar to that of the anti-cyclone, its community had high richness and diversity, comparable with that of the cyclone. Different and contrasting diversity patterns have been previously recorded in cyclonic vs. anti-cyclonic eddies relative to the surrounding waters. This includes reports on a higher diversity in cyclonic eddies (Matis et al., 2014; Pinca and Dallot, 1995), lower diversity in cyclonic eddies (Lavaniegos and Hereu, 2009), higher diversity in anti-cyclonic eddies (Dufois et al., 2016), and lower diversity in anti-cyclonic eddies as found in the majority of the studies (Holliday et al., 2011; Isari et al., 2011; Liu et al., 2020; Matis et al., 2014; Pinca and Dallot, 1997; Seguin et al., 1994). These contradicting patterns of diversity might be related to the difference in ages of the respective mesoscale features, as found in our case, or be related to the initial chemical characteristics of the respective environment (i.e., oligotrophic, mesotrophic or eutrophic). Low nutrient levels, as were measured in the anti-cyclone (Table 1), can promote the inter-specific competition on resources, favoring some species at the expense of others, thus decreasing species richness and evenness (Pinca and Dallot, 1997; Pitta et al., 2016; Seguin et al., 1994; Thingstad et al., 2005).

Copepods generally dominate mesozooplankton assemblages, both in terms of abundance and biomass and are important in the transfer of oceanic carbon, and as a food source for higher trophic levels (Frangoulis et al., 2004). Because they are trophically diverse, the richness and diversity of copepods can reflect major changes in underlying
patterns of production in the upper water column (Bonnet and Frid, 2004). In this study, copepod diversity presented a markedly large difference between the species-rich cyclone (44 species) and the species-poor anti-cyclone (6 species). Most of the copepod species in the anti-cyclone were small-body calanoids, e.g., *Clausocalanus* and *Calocalanus* species. Medium and larger size calanoid copepods, such as *Pleuromamma*, *Euchirella*, *Scolecithricella*, *Ctenocalanus*, *Nannocalcnus* and *Mesocalanus* were only present in the cyclone and background stations. Similar diversity patterns were observed in the Liguro-Provençal Basin, cyclonic and anti-cyclonic gyres in the Ionian and Levantine seas and the Black Sea (Pinca and Dallot, 1997; Siokou-Frangou et al., 1997). In contrast to calanoid copepods, the *Oncaea* species were present only in the cyclone; these cruising detritivores likely benefit from the relatively higher phytoplankton biomass and productivity (Figure 3 and Table 1).

Cyclonic structures have been associated with favorable habitats for reproduction and larval recruitment of many fish species, entraining higher larval abundance and diversity (Bakun, 2010; Condie and Condie, 2016; Logerwell and Smith, 2001; Matis et al., 2014; Mullaney and Suthers, 2013). In this study, we found a higher diversity of fish larvae and eggs in the cyclone, mainly including *Engraulis encrasicolus* (the European anchovy). Up-welling regions in the Alboran Sea, the Gulf of Lion and the nearby Catalan Sea, the Adriatic Sea and the North Aegean Sea are known as successful spawning grounds and areas of high productivity of small pelagic fish, mainly anchovy and sardine (Agostini and Bakun, 2002; Palomera et al., 2007; Stergiou et al., 1997). In the impoverished SEMS, the importance of cyclonic eddies as “high productivity islands” for fish reproduction and recruitment might be high. Indeed, our finding suggests that cyclonic eddies may serve as reproduction hotspots and nursery grounds of anchovies.

Other taxonomic groups, specifically chaetognaths, polychaetes, cladocerans and pelagic amphipods and decapods, exhibited higher richness in the cyclone compared to the anti-cyclone. An exception to the higher species diversity within the cyclone was the gastropods that showed higher diversity in the anti-cyclone station. A potential reason could be the thermophilic nature of many of the taxa identified in the anti-cyclone, including the larvae of a Red-Sea Lessepsian invader, *Nerita sanguinolenta*. An adult individual of this species was recently recorded on the Israeli Mediterranean coast for the
first time (Rabi et al., 2020). Mesoscale and sub-mesoscale structures can promote introductions of invasive species or recruitment of harmful species, such as the destructive crown-of-thorn starfish (Miller et al., 2015), the extremely venomous box jellyfish *Irukandji* (Gershwin et al., 2013), and a sea urchin overgrazing the kelp forests (Ling and Johnson, 2009). In the SEMS, anti-cyclonic eddies originate from the alongshore current in the southeastern corner of the basin, in the vicinity of the Suez Canal opening. We can therefore hypothesize that the higher temperatures in anti-cyclonic eddies and their southeastern origin, might facilitate the introduction and spread of the warm-adapted invasive Red-Sea species. This finding has important implications for conservation and management and should be followed by additional research to substantiate the connection between Lessepsian invasive species and hydrodynamic structures in the Mediterranean Sea. Moreover, more studies of mesoscale features through their lifetime are required to improve the predictions of future conditions and to model the productivity of the Mediterranean Sea and other LNLC regimes in light of global climate changes and the need to reduce the atmospheric carbon print.
