Abstract. The ocean takes up 93% of the excess heat in the climate system and approximately a quarter of the anthropogenic carbon via air-sea fluxes. Ocean ventilation and subduction are key processes that regulate the transport of water (and associated properties) from the surface mixed layer, which is in contact with the atmosphere, to the ocean's interior which is isolated from the atmosphere for a timescale set by the large-scale circulation. Using numerical simulations with an ocean-sea-ice model using the NEMO framework, we assess where the ocean subducts water and thus takes up properties from the atmosphere and how ocean currents transport and redistribute them over time and how, where and when they are ventilated. Here, the strength and patterns of the net uptake of water and associated properties are analysed by including simulated sea water vintage dyes that are passive tracers released annually into the ocean surface layers between 1958 and 2017. The dyes' distribution is shown to capture years of strong and weak convection at deep and mode water formation sites in both hemispheres, especially when compared to observations in the North Atlantic subpolar gyre. Using this approach, relevant to any passive tracer in the ocean, we can evaluate the regional and depth distribution of the tracers, and determine their variability on interannual to multidecadal timescales. We highlight the key role of variations in subduction rate driven by changes in surface atmospheric forcing in setting the different sizes of the long-term inventory of the dyes released in different years and the evolution of their distribution. This suggests forecasting potential for determining how the distribution of passive tracers will evolve, from having prior knowledge of the surface air-sea fluxes, with implications for the uptake and storage of anthropogenic heat and carbon in the ocean.

1 Introduction

The ocean absorbs more than 90% of the anthropogenic warming and is the largest, mobile carbon reservoir in the climate system that is accessible on millennial timescales. Ocean ventilation is the process by which air-sea fluxes of properties such as heat and carbon penetrate into the enormous reservoir that is the ocean interior. Waters recently exposed to the atmosphere, that reside in the ocean's surface mixed layer, pass into the ocean's interior; this is balanced by entrainment of waters from the ocean interior into the ocean mixed-layer (Stommel, 1979). The values of mixed layer properties such as temperature and carbon content depend on the rate of this exchange (Abraham et al., 2013; Banks and Gregory, 2006; Iudicone et al., 2016), as well as the uptake from the atmosphere. Indeed, the atmospheric uptake of heat and carbon itself also depends on ocean

ventilation through this impact of exchange on mixed-layer temperature and carbon. Consequently, ocean ventilation plays a
25 key role in modulating climate variability on interannual to decadal (and even centennial) timescales.

Ventilation involves exchange between the surface mixed-layer and the ocean interior (Luyten et al., 1983). This exchange
is effected in reality on all time and space scales, ranging from the global-scale meridional overturning to small scale turbulent
exchange. The larger scale exchanges involve the net-annual transfer of fluid from mixed-layer to interior (the net subduc-
tion) while the smaller-scale exchanges are associated with geostrophic eddies and small-scale turbulence. In ocean models
30 these smaller-scale exchanges are parameterized as diffusive fluxes. Both large-scale "advective" and small-scale "diffusive"
exchanges are key drivers of the uptake of anthropogenic heat and carbon by the ocean (Williams and Meijers, 2019) and their
observed signals have been estimated by the distribution of transient tracers (e.g. CFCs and tritium).

It is not only the rate of exchange between ocean surface mixed layer and interior that is important, but also the length of time
that subducted waters remain in the interior before coming up again and being re-entrained/obducted into the surface mixed
35 layer. For example, as a consequence of anthropogenic warming the subducted waters warm with time as the mixed-layer
warms, so where these warmer waters re-entrain into the surface mixed-layer rapidly within a few years of their subduction
the surface mixed-layer will warm further. Conversely, waters that spend longer in the interior before they obduct will have
subducted earlier when they are still relatively cool, and so these warm the mixed-layer less when they re-entrain.

The fidelity of future climate projections relies on an accurate representation of ocean ventilation and on the ability of
40 the next generation of numerical models to predict transient and regional climate change (Katavouta et al., 2019). Climate
simulations show wide variations in their representation of processes critical to ocean ventilation and its variability, such
as mixed layer depths in the subpolar gyres, and the strength, depth and variability of the Atlantic Meridional Overturning
Circulation (AMOC) (Heuzé, 2017, 2021). Consequently, variable representation of the ventilation process is a major source
of intermodel spread in the projection of carbon and heat uptake (Boé et al., 2009; Frölicher et al., 2015) by the ocean, and
45 consequently regional sea level rise (Kuhlbrodt and Gregory, 2012; Church et al., 1991).

The high-latitude oceans (e.g. subpolar North Atlantic and Southern Ocean), where the densest waters are formed, play a
prominent role in global ventilation, since up to two-thirds of the volume of the ocean interior and more than three-quarters of
the deep ocean are thought to be ventilated at these locations (Khatiwala et al., 2012). Many of these deep waters are ventilated
on long timescales and a substantial fraction of the deep ocean is ventilated in the high-latitude North Atlantic, feeding the
50 lower limb of the AMOC (Lozier, 2010, 2012). Consequently, this region plays a prominent role in transient climate change,
both through the uptake and redistribution of heat, and the long-term sequestration of anthropogenic carbon (Zanna et al., 2019;
Khatiwala et al., 2009).

Differently from the more established view, recent studies using new observations in the subpolar North Atlantic, indicate
the prevailing importance of the deep waters formed in the Irminger and Iceland basins over the Labrador Sea as largely
55 responsible for the observed variability in the overturning (Lozier et al., 2019; Li et al., 2019; Zou et al., 2020; Petit et al.,
2020). The link between the overturning and the buoyancy forcing in the subpolar gyre points to the important role played by
surface forcing (i.e. air-sea fluxes) in establishing the state of the AMOC and suggest the need to investigate the sensitivity of
the AMOC to the observed interannual variability observed in these regions (Petit et al., 2020).

Processes occurring at lower latitudes and in upwelling layers also affect the renewal of water masses in the ocean's interior, indicating a decoupling of ventilation from the overturning circulation. Subduction into the subtropical thermoclines is a major driver of ventilation. Additionally, diapycnal and isopycnal diffusion play an important role in ventilation both at low and high latitudes e.g. in the upwelling regions of the Southern Ocean (Naveira Garabato et al., 2017). This means that dense water formation at high latitudes (and the overturning circulation) may depend on different dynamics and occur at different locations and on different timescales than ocean ventilation, which largely depends on the connection of tracers to the surface ocean (MacGilchrist et al., 2020).

Age tracers that track the length of time since waters have been ventilated have previously been used in numerical models to understand ventilation timescales (England, 1995; Haine and Richards, 1995; Hall et al., 2002) and Lagrangian particle tracking experiments (Van Sebille et al., 2018) have been performed to investigate high-latitude ventilation with a focus on the North Atlantic subpolar gyre (e.g. MacGilchrist et al., 2017, 2020). However, both of these approaches have limitations. Since any "water parcel" is actually made up of a mixture of waters from different sources, in general it has an age distribution rather than a specific single age, while Lagrangian particle tracking cannot fully account for the effects of mixing and diffusive processes. In addition, observational analysis is often based on the interpretation of the distribution of passive transient tracers, such as CFCs, but while the interpretation accommodates advective and diffusive processes, it does generally assume a steady state background ocean circulation.

We carried out numerical simulations where we resolve the interannual variability in both forcing and circulation, and discern the impact that this variability has on the inventory and distribution of a passive tracer. To achieve this, we analyse changes in ocean ventilation using simulated interannually-varying dye tracers, which represent distinct annual sea water vintages. These allow us to explore the links between subduction, ocean circulation and surface forcing on a range of different timescales and globally, by following the pathways of the passive tracers. With our approach, we aim to separate the roles played by deep water formation, ventilation, overturning and how these are driven by surface forcing on interannual to interdecadal timescales.

Our simulations can be used to inform the interpretation of anthropogenically-sourced transient tracers such as chlorofluorocarbons (CFCs; e.g. Haine and Richards, 1995; England, 1995; Hall et al., 2002; Fine et al., 2017) and other derived quantities such as anthropogenic carbon (Khaliwala et al., 2009, 2012, 2013) and excess heat (Banks and Gregory, 2006; Zanna et al., 2019; Zika et al., 2020). This experimental design (see section 2.3) is complementary to Green's function approaches (Haine and Hall, 2002; Primeau, 2005), where there is an assumption about a steady-state circulation and times and locations of ocean ventilation are expressed as probability distributions. Our simulated dye tracers effectively represent an "explicit" Green's function, where the ocean circulation is time-varying and which allows us to estimate the evolution of the pathways and timescales of ocean ventilation. However, our simulations are computationally expensive to run, limiting the horizontal resolution that we can use, since our aim is to generate a set of interannually-varying tracers for 60 years of available atmospheric forcing (i.e. 60 tracers for each year of simulation).

The model, its spin-up, and the experimental design for the injection of the dye tracers are described in section 2. Changes in the dye distribution are shown globally and as a function of latitude and depth in section 3, highlighting the role of interannual variability in the evolution of the different dyes and differences/similarities between the two hemispheres. The dominant role

of surface forcing in setting these patterns and its implications for the interpretation of observational data, as well as potential
95 drivers of longer-term changes and larger-scale signals, are discussed in sections 4 and 5.

2 Methods

2.1 Ocean-ice model

Numerical simulations are run using a global configuration of the Nucleus for European Modelling of the Ocean model s
(NEMO Madec, 2014) ocean model, which is coupled to the Los Alamos sea-ice models (CICE Rae et al., 2015). We use
100 ORCA1, which has a horizontal resolution of 1° (approximately 73 km) and 75 vertical levels, where the thickness increases
vertically, from 1 m at the surface to 200 m at depth. We prefer not to use a higher resolution version because of the heavy
computational requirements of the simulations.

This model configuration involves a vertical mixing scheme based on the turbulent kinetic energy model of Gaspar et al.
(1990), together with Redi isoneutral mixing (Redi, 1982) with diffusivity of $1000 \text{ m}^2 \text{ s}^{-1}$ and Gent and McWilliams (1990)
105 eddy parameterization with a coefficient dependent on the local Rossby radius and Eady growth rate (Held and Larichev, 1996).
Temperature, salinity and tracers are advected with the total variance dissipation scheme (Cravatte et al., 2007), a second-order,
two-step monotonic flux corrected scheme (FCT) with moderate numerical diffusion. More complete descriptions of ORCA1
and a comparison of its performance with configurations with different horizontal resolutions, can be found in Storkey et al.
(2018) and Kuhlbrodt et al. (2018). ORCA1 also makes up the physical ocean component of the coupled UK Earth system
110 model (UKESM1), contributing to the sixth Coupled Model Intercomparison Project (CMIP6), as described in Yool et al.
(2020).

Our ocean-ice simulation is forced with the JRA55-do surface atmospheric dataset (Tsujino et al., 2018) that is based on the
Japanese 55-year Reanalysis (JRA-55 Kobayashi et al., 2015) and it is spun up following the Ocean Model Intercomparison
Project (OMIP) protocol (Griffies et al., 2016), which recommends running five cycles of the atmospheric forcing, starting
115 from a motionless ocean state with climatological temperature and salinity distribution. Each cycle lasts 60 years (the length
of the available atmospheric forcing for the version used of JRA-55, from 1958 to 2017), and our diagnosis focuses on the last
(fifth cycle), with the previous four cycles (240 years) used for spin-up. This OMIP protocol allows for meaningful comparison
between different models (e.g. Danabasoglu et al., 2014), although there may still be drifts in many ocean properties (Griffies
et al., 2016).

120 Our model configuration gives an AMOC streamfunction of $\sim 12 \text{ Sv}$ (where $1 \text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1}$), which is lower than
the latest RAPID array estimates (between $\sim 17\text{--}20 \text{ Sv}$, Moat et al., 2020), but is not uncommon given the relatively coarse
resolution of the model (e.g. Storkey et al., 2018; Hirschi et al., 2020).

All physical variables and those for the dye tracers are output and stored as monthly means.

2.2 Mixed layer depth

125 The representation of the mixed layer in the model is of particular interest for our analysis, given its key role in driving ocean
ventilation (Pedlosky and Robbins, 1991). Therefore, we compare this simulated quantity from the NEMO output with the
objectively-analysed EN4 dataset (Good et al., 2013) and an optimally-interpolated Argo dataset (updated following Desbruy-
eres et al., 2017). For all datasets and for the time period 2004-2017, the maximum mixed layer depth (Figure 1) is calculated at
each gridpoint, using a variable density threshold associated with a 0.2°C decrease in temperature, and representing the depth
130 of the base of the winter mixed layer, as defined in (Clément et al., 2020).

The model reproduces the deep winter mixed layers both in the North Atlantic subpolar gyre and in the sub-Antarctic
mode water formation regions, as well as along the Antarctic coast (Figure 1a) which is not captured in the EN4 and Argo
datasets (Figures 1b,c,d) due to limited observational capability under ice. However, it is known that the NEMO model is
characterised by excessively strong convection in the Labrador and Irminger Seas, down to depths that are much higher than
135 what is measured in observations (Figure 1c), even at higher horizontal resolutions (MacGilchrist et al., 2020; Marzocchi
et al., 2015; Rattan et al., 2010) and overproduction of Labrador Sea Water is also found in other 1° ocean-ice models when
compared to observations (Li et al., 2019). This results in some overestimation in the mixed layer depth in the North Atlantic
subpolar gyre, but globally the model shows good agreement with observations; deep mixed layers can also be observed along
the pathway of the Gulf Stream and Kuroshio Current, both in the model and in the observations, although in the Atlantic
140 between ~40-60°N the simulated mixed layer is largely shallower than in the observations (Figure 1c).

There are large differences in the simulation of the magnitude and variability of the (A)MOC in numerical models, both at
lower and higher resolutions (e.g. Hirschi et al., 2020; Li et al., 2019). There are also substantial discrepancies in simulating the
mixed layer depth, especially in high latitude regions, and in the representation of water masses, as clearly shown for Labrador
Sea Water (Li et al., 2019). Climate models are also known to struggle with the representation of dense water formation in the
145 Southern Ocean, especially at lower resolutions (Heuzé et al., 2013), which will have an impact on the rates and dynamics of
ventilation.

2.3 Dye tracer injection

In this study we aim to resolve the pathways and the inventories of ventilated waters after they leave the mixed layer. This
is achieved by using a set of annually-distinct dye tracers that are introduced in each year of the last (fifth) cycle through the
150 surface forcing, meaning that the effective model spin-up is 240 years and the simulation with passive tracers is 60 years, which
is the length of the available atmospheric forcing for the version used of JRA-55 (from 1958 to 2017).

In these simulations, the dye tracers are released uniformly across the global ocean, with a 6-month hemispheric offset,
since tracer injection starts during the summer in each hemisphere (i.e. starts in January and ends in December in the Southern
Hemisphere and starts in July and ends in June in the Northern Hemisphere). A transition zone is introduced between 20°N
155 and 20°S, where the start and end of the release year increase day by day linearly moving northwards; i.e. the release year at a

given latitude begins on the year day-number (days from 1 January) that increases linearly between 20°S and 20°N from zero to 181 (the number of days between 1 January and 1 July), and similarly for the end of the release year.

Each dye tracer is injected throughout its release year (its 'vintage') by relaxing the tracer's concentration to a value of 1 throughout the top seven vertical levels (down to ~10m). The relaxation time is $T_r = \frac{T_{r0}}{1-a_i}$, where $T_{r0}=7200$ s (the leapfrog
160 timestep) is the smallest relaxation time that still remains stable. To represent the ability of ice cover to insulate the ocean from air-sea gas exchange, the relaxation time is increased by the reciprocal of the water fraction $1-a_i$ with a_i the ice fraction. With the depth interval of 10 m, this implies a piston velocity of $1.39 \times 10^{-3} \text{ m s}^{-1}$, (120 m day^{-1}) without ice (much faster than a typical gas exchange piston velocity of 2.4 m day^{-1}), ranging down to a velocity of 2.4 m day^{-1} in regions of maximum ice-cover with $a_i=0.02$. After injection into the interior, each tracer continues to propagate through the ocean, driven by advective
165 and diffusive components of the simulated circulation. After its release year, each tracer is relaxed back to zero in the upper 10 m, resulting in a systematic loss of the globally integrated tracer inventory over the simulation. This is presented schematically in Figure 2, where dye N is only injected in release (vintage) year N, while dye N+1 only starts being injected in release year N+1, and so on for the following years (from N+2 to N+59).

For the analysis presented in section 3, we use a subset of dyes, injected in 1958 to 1993, so that we can follow their evolution
170 from the year of injection and for 25 years of simulation for each one of the 36 vintages, allowing us to investigate the role of interannual variability and pathways from annual to multidecadal timescales.

2.4 Dye diagnostics

The dye concentration, c , at any point (or in the model, in a gridbox) represents the fraction of water at that point that was exposed to the surface in the dye's release winter (vintage). The natural unit for the dye concentration is, therefore, dimensionless
175 (a fraction, so $0 < c < 1$). Then the total globally-integrated inventory of dye $C_{global} = \iiint c \, dV$ represents the total volume of water exposed to the surface in the release year. Similarly, the 'ventilation depth' $C(\phi, \lambda) = \int c \, dz$ (where ϕ and λ are latitude and longitude) represents the volume of such ventilated waters per unit area, and so has dimensions of depth (m). It can be thought of as the depth of a notional layer in which the vertically-integrated inventory is concentrated with a dye concentration of $c=1$. In the first year this represents the mixed-layer depth as $c \approx 1$ in the mixed-layer and $c \approx 0$ below it. We find it useful to
180 define globally- (and hemispherically-) averaged ventilation depths that relate to the globally- and hemispherically-integrated inventories. In subsequent years these averaged ventilation depths progressively decrease as the dye reenters the mixed layer and is lost (set to zero).

3 Results

Our setup allows us to identify when and where water masses were last ventilated and to investigate the role of interannual
185 variability in determining the tracers distribution, as well as unpicking the role of surface forcing and ocean circulation in setting these pathways and timescales.

3.1 Global dye distribution

Here we consider the dye injected in each year separately. For each year, the dye concentration peaks during the winter in each hemisphere (where it is injected) and the ventilation depth in the year of injection is always higher in the Southern Hemisphere (Figure 3). In each hemisphere, the interannual differences between each of the dyes largely derives from changes in the background ocean circulation and the effect of surface forcing on the mixed layer depth at the time of injection, as the dyes are independent of each other and identify different sea water vintages for each year.

After the first year of dye injection, the interannual variability in the ventilation depth peak between the different vintages mostly reflects the variability in mixed layer depth in different years, driven by the surface forcing (see Figure 3). For the rest of the analysis the main focus will remain on two chosen timescales, of 3 and 25 years (which are discussed further in section 3.2), by using a subset of the dye tracers (as introduced in section 2.3). Three years after injection, the vintages represent seawater that has moved below the base of the mixed layer and been subducted, while after 25 years they correspond to water that has flowed out of the upper ocean.

Globally, during the first year when the dye is injected, the highest tracer concentrations can be seen in regions that correspond to the deepest mixed layers (see Figure 1a), such as the subpolar North Atlantic near the locations of deep-water formation from the Labrador and Irminger Seas to the Nordic Seas, as well as along the paths of the Gulf Stream and Kuroshio and in the Mediterranean Sea (Figure 4a). Strong dye uptake can also be seen in the Subantarctic mode water (SAMW) formation regions in the Southern Hemisphere and along the Antarctic coast and in the Weddell Sea, where dense water is formed (Figure 4a).

Three years after injection, the dye is spreading prominently in the North Atlantic subpolar gyre (Figure 4b) and after 25 years it has reached the entire basin, while it is also starting to spread southward along the western boundary (Figure 4c). It is, however, worth remembering that boundary currents are not particularly well-represented at 1° horizontal resolution, which will affect the dye distribution (e.g. England, 1995). In the Southern Hemisphere, the uptake of dye can still be clearly identified in the SAMW formation regions after 3 and 25 years (Figures 4b, c). Concentrations in the Arctic are likely too high (Figures 4b, c), possibly as an artifact due to the model resolution, meaning that the dye accumulates in this region due to restrictions in the flow through bathymetric features that are poorly represented at 1° . However, these concentrations decrease over time, as the dye excess is slowly being ventilated out of the basin (not shown) which has a relatively small volume (Figure 5b).

Within 60 years (the end of the simulation), the core of the dye in the Atlantic has reached the deep ocean (down to ~ 3000 m) between 20 and 50° N, while in the top 1000 m it has spread to $\sim 40^\circ$ S (Figure 4d). The dye inventory evolves differently over time in each basin and most of it can be found in the Atlantic on the time scales that we are examining (Figure 5a), despite the substantially smaller volume of the Atlantic than the Pacific (Figure 5b). Within 60 years after injection, the dye is accumulating faster in the Southern Ocean than in other basins (Figure 5a), as it is reaching down to greater depths faster (Figure 4d). As previously discussed, models are also known to struggle with the representation of dense water formation in the Southern Ocean, especially at the coarse resolution of this model, which may explain the low concentrations (and small inventory) of tracer in the deep Southern Ocean (Figure 4d).

3.2 Interannual variability in ventilation depth and ventilation timescales

By using a subset of dyes, from 1958 to 1993, we can follow their evolution from the year of dye injection and for 25 years of simulation for each one of these 36 vintages. Looking at the evolution of the dyes as the anomaly from the mean ventilation depth (for the 1958-1993 time period) highlights the differences between the independent vintages that are due to interannual variability (Figure 6). The strongest differences from the mean p to ~ 10 m in the Southern Hemisphere develop within the first three years, but these reduce substantially or at least stabilise by 3 years after injection in both hemispheres (Figure 6; 7a). However, after 3 years of the simulation the differences remain relatively large in the Northern Hemisphere, while they fall off in the Southern Hemisphere. After 25 years (Figure 7b) ventilation depths still vary by up to 3 years between vintages in the Northern Hemisphere, while in the Southern Hemisphere differences reduce to within $\sim \pm 1.5$ m.

Positive anomalies (i.e. ventilation depths higher than the mean) characterise the later years/vintages (1980s/1990s) in the Northern Hemisphere, while this is opposite in the Southern Hemisphere, where this is the case for earlier years (1960s); similarly, for the negative anomalies (Figure 6). For all vintages the ventilation depth is higher in the Southern Hemisphere after three years than in the Northern Hemisphere (Figure 7a), as also shown for the year of injection (Figure 4a). Years with ventilation depths that are higher than the mean are not necessarily the same in both hemispheres, representing the different response to the surface forcing and the background circulation (e.g. stratification) and local process at play. On this time scale, the vintages represent seawater that has been subducted after injection and then has moved below the base of the mixed layer.

In the Northern Hemisphere, the vintages from the early 90's have relatively high values, which correspond to years of observed strong convection in the Labrador Sea (e.g. Yashayaev, 2007; Rhein et al., 2017). Values in the Northern Hemisphere are actually above or very close to the mean for the entire period from the early 80's to the early 90's, while in the Southern Hemisphere ventilation depths higher than the mean can mainly be seen for the earlier period until the late 70's (Figure 7a).

Even though the mean hemispheric ventilation depth values are much closer to one another 25 years after injection, the early 90's vintages in the Northern Hemisphere are now the highest, as well as for the early 80's (Figure 7b), which also stood out at the 3-year timescale. This suggests that the response after 25 years, when the vintages represent water that has now flowed out of the upper ocean, is still strongly affected by the processes shaping the mixed layer at the time of dye injection and for the subsequent 2-3 years.

To further investigate this apparent link between the processes affecting subduction close to the time of dye injection and over the following two decades, we correlate the ventilation depth for the two timescales of 3 and 25 years (Figure 8). These show high correlation ($R^2 \geq 0.7$) for both hemispheres, which confirms that the conditions close to the time of injection (i.e. mixed layer depth and background circulation) are driving the amount of seawater being subducted, but also that this signal persists over time and that its inventory over 25 years is strongly related to that initial forcing.

Ventilation in the Northern Hemisphere appears to be twice as effective as in the Southern Hemisphere (see the slope for the correlations in Figures 8a, c) which could be thought of as a rate of erosion for the ventilated water masses or as a "ventilation efficiency". This means that subducted waters are exported (and isolated) away from deep mixed layer regions faster in the Northern than the Southern Hemisphere. The residuals of the correlations (Figures 8a, c) also highlight some of the longer-term

255 variability, particularly in the Northern Hemisphere, where the residuals for the "later" vintages corresponding to the early 90's
appear to be rising (Figure 8b).

3.3 Longer-term effect of the initial surface forcing on dye distributions

Dyes that were injected in years characterised by stronger convection result in deeper ventilation depths after 3 and 25 years
(Figure 7), but this also impacts the evolution of the tracer vertical distribution over time. This is shown for seven of the
260 vintages (highlighted in Figure 8) analysed so far, covering a range of higher and lower (than the respective hemispheric mean)
ventilation depths (Figures 9 and 10).

The strongest differences in the tracer latitudinal distribution between different vintages develop in the Northern Hemisphere
subtropical gyres (Figure 9a) and are dominated by the North Atlantic (not shown), which can be expected on these time scales
(i.e. 25 years after injection). The 1992 vintage stands out and it corresponds to a period of strong convection in the Labrador
265 Sea, as discussed in section 3.2 and shown in Figure 7, but 1982 and 1972 also have a relatively high peak around 40°N. In the
Southern Hemisphere, there are smaller differences between the different vintages, but as expected (see Figure 7a) the highest
peak corresponds to the dye injected in 1962 (dominated by the signal in the Pacific, not shown).

The vertical distribution of the tracer (Figure 9b) is characterised by two prominent peaks, where the shallower one at around
500m is present in all ocean basins but dominated by the inventory in the Pacific (not shown). The deeper peak below 2000m
270 is driven by the variability in the North Atlantic (not shown) and in fact the highest values are reached in 1992 and 1982.
Differences in the Atlantic are also shown along a north-south section in the centre of the basin (see Figure 4c) for two of
the vintages 25 years after their injection (Figure 10), one from a strong Northern Hemisphere ventilation year (1992) and a
weak one (1987). The tracer reaches deeper and with higher concentrations when they are injected in years characterised by
strong convection in the subpolar North Atlantic (Figure 10a) and the distribution is also lower in the top ~1000 m both in the
275 Northern and Southern hemispheres for the year with weaker convection (Figure 10b).

4 Discussion

When considering ocean ventilation and how it regulates the dynamics of tracers and their connection to the surface ocean, it
is important to remember that it is driven by processes occurring at lower latitudes, as well as the overturning circulation and
dense water formation in the high-latitude ocean and (Naveira Garabato et al., 2017; MacGilchrist et al., 2020). In particular,
280 subduction into the subtropical thermoclines drives substantial ventilation. Additionally, diapycnal and isopycnal diffusion play
an important role in ventilation both at low and high latitudes (Naveira Garabato et al., 2017). These aspects are included in
our simulations, by using passive tracers that reproduce both the advective and diffusive components of the circulation, and
this is highlighted by our analysis of interannual to multi-decadal subduction and ventilation.

Despite the known biases for NEMO, such as the too-deep mixing in the Labrador Sea (as discussed in section 2.2) and
285 the fact that not all processes can be simulated accurately at resolutions that are not eddy-resolving, this does not affect our

results correlating ventilation depth on different timescales and highlighting the dominant role of surface forcing in setting the evolution of the tracer distribution and inventory.

4.1 The fingerprint of surface atmospheric forcing

The dye uptake in the first (injection) year largely reflects the state and variability of the mixed layer during the season of active convection, which is driven by the surface forcing in that year (Figures 1a and 4a) and the stratification in that year (reconditioning). Three years after injection, the amount of dye that has reached below the base of the mixed layer is also dependent on other factors, linked to both lateral mixing and the surface forcing in the years immediately following injection. This determines how much dye is retained, since a deepening of the mixed layer in the winter following the injection year ($N+1$; see Figure 2) will ventilate a larger portion of the vintage from the previous year (N ; see Figure 2) and effectively reduce the dye concentration (since in our setup it will be reset to zero when ventilated). This contributes to the interannual variability on this timescale.

The correlation between dye retention after 25 years and the background conditions close to the time of injection (just after the strongest interannual differences have decreased; see Figure 6) highlights the key role of the surface atmospheric forcing in driving long-term ocean ventilation, and more broadly, in determining the distribution of passive tracers over time. Since the variability in ventilation near the time of dye injection sets the long-term variability for the dye inventory, there is potential for forecasting how the distribution of a tracer in the ocean will evolve in the future, from a prior knowledge of the surface air-sea fluxes.

Finally, the strong correlations in ventilation depths between 3 and 25 years after injection in both the Northern and Southern hemispheres (Figure 8) imply that, given the strong interannual variability in the initial surface forcing, it is this variability that will continue to dominate on longer time scales, largely overriding the different processes that drive how passive tracers are removed or taken up in the two hemispheres. The Northern Hemisphere is characterized by more persistent anomalies, since the ventilated waters penetrate more deeply where they are better isolated from surface influence while in the Southern Hemisphere the anomalies are initially stronger (Figure 6), but then dissipate faster than in the Northern Hemisphere, partly due to the more effective mixing along sloping isopycnals in the Southern Ocean. This means that the tracer eventually gets mixed back and ventilated even when the initial amount that is subducted is substantially higher than the mean, while the dye remains in the interior for longer in the subpolar North Atlantic once it has reached a deeper horizon (Figures 9 and 10).

4.2 Longer-term and large-scale signals

The strong interannual variability that characterises ventilation in the Northern Hemisphere on these timescales (Figure 7) is largely driven by the Irminger, Nordic and Labrador Seas (Figures 4a,b), which are the sites of most active deep convection in the winter months (e.g. Lozier, 2010) and are characterised by ventilation anomalies that persist for longer than in the Southern Hemisphere (Figure 6).

There is coherent structure in the residuals of the correlation between Northern Hemisphere ventilation depth close to the time of dye injection and 25 years later and the residuals deviate from the trend (rise) for the vintages corresponding to the

early 90's (Figure 8b). We expect that the role of surface buoyancy forcing through air-sea fluxes, as well as modes of climate
320 variability that may affect convection in the subpolar North Atlantic (e.g. North Atlantic Oscillation - NAO - or Atlantic
Multidecadal Variability - AMV) should already be captured by the correlation itself (Figure 8a). However, these will, in turn,
also affect the background circulation. We examine whether there is a relationship between the residuals and the strength of
the large-scale circulation (AMOC). The hypothesis is that a stronger circulation (AMOC) might also be linked with moving
water more effectively away from the ventilation site and reducing the rate at which dye is returned to the mixed layer and
325 thus removed from the system. We consider the correlation between the residuals in the Northern Hemisphere and the AMOC
at 26°N and 1000 m depth (to be comparable to estimates for the RAPID array; Figure 9). There is a correlation ($R^2 = 0.45$)
between the residuals and the AMOC in the year of injection, while that with the AMOC 25 years later is much weaker ($R^2 =$
0.2).

The mechanism behind the connection that we find between the strength of the AMOC at 26°N and the residuals of the
330 correlation for the Northern Hemisphere (Figure 11) is not fully clear. We also tested this correlation with the AMOC at higher
latitudes (e.g. 45°N; not shown), but despite being closer to the sites of deep convection in the subpolar North Atlantic, the
correlation is much weaker. It is, however, harder to assess and interpret AMOC changes at these higher latitudes, especially in
depth rather than density space (Zou et al., 2020; Hirschi et al., 2020). There are also large differences in the simulation of the
magnitude and variability of the (A)MOC across different numerical models, both at lower and higher resolutions (e.g. Hirschi
335 et al., 2020; Li et al., 2019); as well as substantial discrepancies in simulating the mixed layer depth, especially in high latitude
regions, and in the representation of water masses, as clearly shown for Labrador Sea Water (Li et al., 2019). Both in models
and observations, the relationship between the hydrographic variability in the subpolar North Atlantic and the AMOC has also
been shown to quickly deteriorate downstream of the Labrador Sea (e.g. Zou et al., 2019; Li et al., 2019).

While it would be desirable to perform longer simulations with passive tracers and assess their uptake on centennial time
340 scales, our results highlight how this would be problematic. In fact, the tracer's pathways, inventory and distribution will be
strongly dependent on the initial surface forcing, when the tracer enters the ocean, especially for the Northern Hemisphere (see
Figures 9 and 10). This means that the cumulation of the inventory of a simulated tracer over time will provide an aliased view
of its evolution. At the same time, it is at present too computationally-expensive to introduce interannually-varying tracers to
resolve the full variability on such long timescales.

345 5 Summary and conclusions

We have used a set of interannually-varying passive dye tracers in an ocean-ice model to explore pathways and time scales of
ocean ventilation. This is a computationally-expensive approach, but it allows us to fully capture the pathways of subducted
waters after they leave the mixed layer.

The Southern Hemisphere shows more variability in ventilation depth just after the tracer injection, while the Northern Hemi-
350 sphere is characterised by higher variability in the 25-year inventory, highlighting different ventilation efficiencies and timescales.
Subducted waters are exported faster in the Northern than in the Southern Hemisphere, but the correlation between ventilation

depths after three and 25 years is strong in both hemispheres. This means that the strong interannual variability in the initial surface forcing will dominate on longer time scales, and largely override the different processes that drive the uptake and export of passive tracers.

355 Our results highlight the key role played by surface forcing near the time when a tracer enters the ocean in setting the long-term variability of its inventory and determining the pathways and timescales of their uptake by the ocean. This has important implications for the interpretation of observations that only capture snapshots of the circulation and also offers potential to forecast changes in the pathways and uptake of tracers by the ocean, such as anthropogenic carbon and heat (e.g. Zanna et al., 2019; Bronselaer and Zanna, 2020), with important consequences in estimating changes in their inventories and long-term
360 storage and sequestration.

Given the deficiencies of our coarse-resolution model, it would be desirable but highly computationally expensive to apply our method to a fully eddy-resolving setup. The use of higher resolution models would prove challenging even with a smaller subset of interannually varying tracers. Comparisons between different models would also be insightful, but once again not easy to achieve due to the computational costs; in this case, the use of offline Lagrangian trajectories could be a satisfactory
365 compromise. Finally, it would be feasible, but once again computationally very expensive, to apply our methodology at 1° resolution with tracers that are released from a set of surface patches that represent the source regions of different water masses (following the methodology of e.g. Khatiwala et al., 2009, 2012, 2013) that has been used for the interpretation of derived quantities such as anthropogenic carbon.

Author contributions. AM and GN designed the ocean-ice simulations with tracers. AM ran the simulations and analysed the data. LC
370 computed the analysis for the data shown in Figure 2. All co-authors contributed to the interpretation of the data and to the writing of the manuscript.

Competing interests. The authors declare no competing interests
