Abstract. Use of an ocean parameter and state estimation framework—such as the Estimating the Circulation & Climate of the Ocean (ECCO) framework—could provide an opportunity to learn about the spatial distribution of the diapycnal diffusivity parameter (κ_ρ) that observations alone cannot due to gaps in coverage. However, we show that the assimilation of existing in situ temperature, salinity, and pressure observations is not sufficient to constrain κ_ρ estimated with ECCO, as κ_ρ from ECCO does not agree closely with observations—specifically, κ_ρ inferred from microstructure measurements. We investigate whether there are observations with more global coverage and well-understood measurement uncertainties that can be assimilated by ECCO to improve its representation of κ_ρ . Argo-derived κ_ρ using a strain-based parameterization of finescale hydrographic structure is one potential source of information. Argo-derived κ_ρ agrees well with microstructure. However, because Argo-derived κ_ρ has both measurement and structural uncertainties, we propose dissolved oxygen concentrations as a candidate for future data assimilation with ECCO. We perform sensitivity analyses with ECCO to test whether oxygen concentrations provide information about κ_ρ . We compare two adjoint sensitivity calculations: one that uses misfits to Argo-derived κ_ρ and the other uses misfits to dissolved oxygen concentrations. We show that adjoint sensitivities of dissolved oxygen concentration misfits to the state estimate’s control space typically direct κ_ρ to improve relative to the Argo-derived and microstructure-inferred values. However, assimilation of dissolved oxygen concentrations would likely not serve as a substitute for assimilating accurately measured κ_ρ .

1 Introduction

In this paper, we consider the challenges with using observational data products to better inform a data assimilation framework—and, ultimately, better inform us—about the global distribution of ocean mixing. Ocean models must parameterize the unresolved, turbulent diffusion of oceanic tracers because they are unable to resolve the scales of the processes responsible for

20 mixing. Ocean mixing is typically conceptualized in terms of diffusion along and across isopycnal surfaces, and is associ-
ated with the transport of isopycnal thickness (or bolus). Ocean models often represent mixing with three parameters: the
across-isopycnal mixing parameter (diapycnal diffusivity; *Munk and Wunsch* (1998)), the along-isopycnal mixing parameter
(Redi coefficient; *Redi* (1982)), and the eddy isopycnal thickness transport parameter (Gent-McWilliams coefficient; *Gent and*
McWilliams (1990)). Diapycnal mixing is an essential component in explaining the observed oceanic stratification (*Munk and*
25 *Wunsch*, 1998; *Gnanadesikan*, 1999; *Scott and Marotzke*, 2002). Changes in the background diapycnal diffusivity (*Dalan et al.*,
2005; *Krasting et al.*, 2018; *Hieronymus et al.*, 2019; *Sinha et al.*, 2020), Redi coefficient (*Gnanadesikan et al.*, 2015; *Ehlert et*
al., 2017), and Gent-McWilliams coefficient (*Danabasoglu and McWilliams*, 1995) are known to have a profound influence on
climate simulations through alterations in the response to surface flux perturbations and changes in ventilation rates. However,
the spatiotemporal variabilities found in previous studies of the Redi coefficient (*Abernathy et al.*, 2013; *Bates et al.*, 2014;
30 *Forget et al.*, 2015b; *Cole et al.*, 2015; *Busecke and Abernathy*, 2019; *Groeskamp et al.*, 2020) and Gent-McWilliams coeffi-
cient (*Forget et al.*, 2015b; *Katsumata*, 2016; *Bachman et al.*, 2020) fields are virtually absent in ocean models. There is also
a dearth of independent observations with which to assess their observationally-derived values (*Cole et al.*, 2015; *Katsumata*,
2016; *Roach et al.*, 2018; *Groeskamp et al.*, 2020), and these values cannot be easily compared with those in models. For
instance, it is unclear how to compare Redi coefficients derived from observations with those from models because they are
35 expected to vary with horizontal resolution. Also, the rotational component of eddy transport is not treated the same in many
models as in the observationally-derived Gent-McWilliams coefficient product. For these reasons, we focus on the diapycnal
diffusivity field— κ_ρ hereafter—in this study.

Parameterizations for κ_ρ (*Gaspar et al.*, 1990; *Large et al.*, 1994) have allowed for a spatiotemporally-varying κ_ρ field,
but assessing the performance of these parameterizations has been challenging due to a profound lack of observations. Until
40 recently, the only available observational information about κ_ρ came from tracer release experiments (*Ledwell and Watson*,
1991; *Polzin et al.*, 1997; *Messias et al.*, 2008) and microstructure (i.e., the scales over which molecular viscosity and diffusion
are important) measurements of velocity shear (e.g., *Waterhouse et al.* (2014)) or temperature variability (e.g., *Gregg* (1987)).
These data are infrequently sampled and cover a relatively small portion of the ocean, but are independent observations with
which to compare the more recent global mixing data products. While our understanding of the global distribution of κ_ρ has
45 been transformed by the use of theories to derive κ_ρ from limited observations (*MacKinnon et al.*, 2017; *Whalen et al.*, 2020),
none of these observations have been assimilated by existing ocean modeling systems to constrain the κ_ρ field because they are
not direct measurements. Currently, the only information about κ_ρ comes from temperature, salinity, and pressure observations
in ocean data assimilation systems. If these observations were collected at every location and depth of the ocean, there could
be sufficient information to constrain κ_ρ (*Groeskamp et al.*, 2017), but historically, there are spatiotemporal gaps—the reason
50 why we need a data assimilation framework in the first place.

We use the Estimating the Circulation & Climate of the Ocean (ECCO) parameter and state estimation framework to eval-
uate how near-global, observationally-derived κ_ρ can be used to inform ocean models. The aim of the ECCO framework is to
reconstruct the recent history of the ocean (the “state estimate”) by filling in the gaps between incomplete observations, which
are often sparse and aliased, through data assimilation techniques. The state estimate is much like a reanalysis product (*Heim-*

55 *bach et al.*, 2019), but the state estimation framework overcomes some shortcomings by requiring dynamical and kinematical consistency (*Stammer et al.*, 2016). The version 4, release 3 of ECCO (ECCOv4r3; *Fukumori et al.* (2017)) state estimate in our case is achieved by fitting a general circulation model to available observations in a weighted least squares sense (*Wunsch*, 2006; *Forget et al.*, 2015a). The model-data misfit (objective or “cost function”) is minimized by varying (i.e., inverting for) a set of uncertain control variables, all of which are independent inputs to the model equations being solved. Importantly for our goal of parameter estimation, the set of control variables may consist not only of initial and boundary conditions, but also of (spatially-varying) model parameters, such as the three used to represent ocean mixing (*Liu et al.*, 2012; *Forget et al.*, 2015a). Since it remains under-explored how well κ_ρ , in particular, is constrained in ECCOv4r3 and how we can provide additional information about κ_ρ , this is the subject of the current study.

To assess whether observations other than temperature, salinity, and pressure can provide useful constraints on the κ_ρ field in ECCOv4r3, we must first perform comparisons of κ_ρ from ECCOv4r3 with κ_ρ from observations, which has not previously been done. We use κ_ρ inferred from microstructure (*Waterhouse et al.*, 2014) and derived from Argo floats (*Whalen et al.*, 2015) to determine whether the ECCO framework needs to improve its κ_ρ using observational constraints (Sections 3.1 and 3.2). It would be possible to assimilate values for κ_ρ derived from theories, which have been shown to agree well with microstructure observations (*Whalen et al.*, 2015). However, because κ_ρ is derived and not measured, an ocean data assimilation system would need to account for both their structural and measurement errors, and their structural uncertainties are not yet well-understood. An alternative approach to constraining κ_ρ is to find a quantity measured with in situ observations (e.g., a transient tracer, as proposed here) that provides information about κ_ρ . Thus, we perform model experiments in forward plus backward (“adjoint”) mode to determine whether transient tracer data and observationally-derived κ_ρ provide similar information about how to adjust κ_ρ (Section 3.3). This will help determine whether κ_ρ could be improved by assimilating transient tracer data in a future optimization of an ocean state estimation framework.

2 Methods

2.1 Observationally-derived data products and measured data

2.1.1 Diapycnal Diffusivities

We make use of multiple data sets for κ_ρ derived from observations. (We distinguish between “observations” that are measured quantities using in situ instruments and observationally-derived values, which use measured quantities and a theory to derive values. The former data have only measurement uncertainties, while the latter data have both measurement and structural uncertainties.) These data sets—listed in Table 1—contain values equatorwards of 75°S and 75°N, and deeper than about about 250 meters because the method does not yield accurate results in the presence of strong upper-ocean density variability (e.g., *D’Asaro* (2014)).

κ_ρ is routinely inferred from the velocity shear measured using microstructure profilers (*Waterhouse et al.*, 2014). We use microstructure-inferred κ_ρ —referred to as $\kappa_{\rho,micro}$ hereafter—(*Osborn*, 1980; *Lueck et al.*, 1997; *Gregg*, 1989; *Moum et al.*,

2002; *Waterhouse et al.*, 2014) to evaluate a model's κ_ρ . (We further distinguish “observationally-inferred” values, which are from the currently accepted method of observing a quantity such as κ_ρ but are not measured, and “observationally-derived” values because the latter data depend on a method that requires additional assumptions.) $\kappa_{\rho,micro}$ are based on an expression
90 for the isotropic turbulence field, which is proportional to the viscosity of water and the velocity shear resolved to dissipative scales (*Thorpe* (2007); and references therein). The depth ranges of the data collected by *Waterhouse et al.* (2014) go from the upper several hundred meters to the full water column. The profiles are seasonally biased at higher latitudes and span decades. There are thousands of vertical profiles that comprise this data set, with samples being taken in North Pacific Ocean, North Atlantic Ocean, tropical Pacific, near Drake Passage, near the Kerguelen Plateau, and in the South Atlantic Ocean. Many of
95 the profiles were taken in regions with both smooth and rough bottom topography. To compare the microstructure profiles with model output, the nearest neighbors to each model's grid are selected, which reduces the data set to 42 profiles.

κ_ρ values are derived from finestructure observations of temperature, salinity, and pressure using a strain-based finescale parameterization, which has been developed and implemented in different ways (*Heney et al.*, 1986; *Gregg*, 1989; *Polzin et al.*, 1995, 2014), but typically assumes a mixing efficiency of 0.2 (*St. Laurent and Schmitt*, 1999; *Gregg et al.*, 2018).
100 The finescale parameterization assumes that 1) the production of turbulent energy at small scales is due to an energy transfer driven by wave-wave interactions down to a wave breaking scale; 2) nonlinearities in the equation of state, double diffusion, downscale energy transports, and mixing associated with boundary layer physics and hydraulic jumps are neglected; and 3) stationary turbulent energy balance exists where production is matched by dissipation and a buoyancy flux in fixed proportions (*Polzin et al.*, 2014). The implementation by *Whalen et al.* (2015) uses Argo data, assumes a shear-to-strain variance ratio of 3
105 and a flux Richardson number of $R_f = 0.17$, and determines the fraction of turbulent production that goes into the buoyancy flux (and the rest for dissipation). The finestructure method is not expected to be valid in equatorial regions of the ocean, but nevertheless, the κ_ρ product compares well with microstructure near the equator (*Whalen et al.*, 2015). We use the 2006-2014 climatology of *Whalen et al.* (2015)—referred to as $\kappa_{\rho,W15}$ hereafter—which is a gridded product on an approximately $1^\circ \times 1^\circ$ horizontal grid and has three vertical levels: 250-500 meters, 500-1000 meters, and 1000-2000 meters depth. *Whalen et al.*
110 (2015) found that 81% (96%) of their $\kappa_{\rho,W15}$ product is within a factor of 2 (3) of the microstructure measurements. We use this as the basis for the factor of 2-3 uncertainty we cite hereafter.

In addition to the Argo-derived $\kappa_{\rho,W15}$ product, there is ship-based Conductivity, Temperature, and Depth (CTD) hydrography-derived κ_ρ (*Kunze*, 2017)—referred to as $\kappa_{\rho,K17}$ hereafter—that uses the same finestructure parameterization as in the calculation of the $\kappa_{\rho,W15}$ product (see Section 2.2). The vertical resolution of the $\kappa_{\rho,K17}$ product is 256 meters and the horizontal resolution
115 tion is the spacing between each CTD profile. Data are only included in the $\kappa_{\rho,K17}$ product when the square of the buoyancy frequency is greater than $10^{-7} \text{ rad}^2 \text{ s}^{-2}$ and greater than the square of the Coriolis frequency, $\kappa_{\rho,K17} < 3 \times 10^{-3} \text{ m}^2 \text{ s}^{-1}$ is positive, and the depth is deeper than 400 meters.

2.1.2 Dissolved oxygen

In addition to the κ_ρ products, we prepare a tracer for use as a potential constraint on κ_ρ . Dissolved oxygen has vertical
120 gradients that can be resolved by ocean models and has future changes projected to be dependent upon mixing (*Palter and*

Trossman, 2018; Couespel et al., 2019). Oxygen utilization rates within subtropical mode water in the North Atlantic Ocean strongly depend upon vertical mixing (Billheimer et al., 2021). Thus, we choose to include the oxygen climatology from the World Ocean Atlas (2013) in our simulations.

The vertical gradients of these oxygen concentrations, $\partial O_2/\partial z$, are shown in Fig. 1 for the three depth-averaged bins that Whalen et al. (2015) used for their $\kappa_{\rho,W15}$ product. $\partial O_2/\partial z$ is generally smaller in polar regions, and relatively larger and positive landward of the Gulf Stream, in the Norwegian Sea, off the southern coasts of Mexico and India, near the equator in the Atlantic Ocean, and in the Southern Hemisphere's subtropical gyres of the Pacific and Indian Oceans between 250-500 meters depth (Fig. 1a). The largest positive $\partial O_2/\partial z$ fill in the gaps between the subpolar regions and the equator at deeper depths (Figs. 1b,c).

Co-location of $\partial O_2/\partial z$ and the dissipation rates calculated by Whalen et al. (2015) (see their Fig. 3 compared to Fig. 1 of the present study) suggests there may be information about ocean diapycnal mixing—at least through the Osborn (1980) relationship—in oxygen concentrations. The spatial correlation between $\partial O_2/\partial z$ and the dissipation rates is about -0.2 and increases in magnitude on coarser grids. This indicates a possibly non-local relationship between $\partial O_2/\partial z$ and dissipation rates. The spatial correlation between $\partial O_2/\partial z$ and the $\kappa_{\rho,W15}$ is smaller in magnitude—about -0.1 . In general, large dissipation rates and κ_{ρ} values correspond to smaller or more negative $\partial O_2/\partial z$.

2.2 Modeling system

We use the Estimating the Circulation & Climate of the Ocean (ECCO) framework in our analysis. We use this modeling framework for two purposes: 1) to test whether κ_{ρ} from ECCO agrees with Argo-derived and microstructure-inferred κ_{ρ} , given incomplete temperature, salinity, and pressure observations; and 2) to assess whether dissolved oxygen concentrations and observationally-derived κ_{ρ} provide similar information about how to improve the agreement between κ_{ρ} from ECCO and observationally-derived data products. ECCO uses a time-invariant but spatially varying κ_{ρ} field, estimated with an optimization procedure, where κ_{ρ} associated with temperature and salinity are assumed to be identical. Details about the model simulations we perform are summarized in Table 2.

2.2.1 ECCO

The modeling system used here is ECCOv4r3 (Fukumori et al., 2017). The underlying ocean-sea ice model is based on the Massachusetts Institute of Technology general circulation model (MITgcm), which is a global finite volume model. The ECCOv4r3 global configuration uses curvilinear Cartesian coordinates (Forget et al. (2015a) - see their Figs. 1-3) at a nominal 1° (0.4° at equator) resolution and rescaled height coordinates (Adcroft and Campin, 2004) with 50 vertical levels and a partial cell representation of bottom topography (Adcroft et al., 1997). The MITgcm uses a dynamic/thermodynamic sea ice component (Menemenlis et al., 2005; Losch et al., 2010; Heimbach et al., 2010) and a nonlinear free surface with freshwater flux boundary conditions (Campin et al., 2004). The wind speed and wind stress are specified as 6-hourly varying input fields over 24 years (1992-2015). There are 14-day adjustments to the wind stress, wind speed, specific humidity, shortwave downwelling radiation, and surface air temperature. These adjustments are based on estimated prior uncertainties for the chosen atmospheric

reanalysis (*Chaudhuri et al.*, 2013), which is ERA-Interim (*Dee et al.*, 2011). The net heat flux is then computed via a bulk formula (*Large and Yeager*, 2009). A parameterization of the effects of geostrophic eddies (*Gent and McWilliams*, 1990) is used. Mixing along isopycnals is accounted for according to the framework provided by *Redi* (1982). Vertical mixing–diapycnal plus the vertical component of the along-isopycnal tensor—is determined according to the *Gaspar et al.* (1990) mixed layer turbulence closure and simple convective adjustment.

Initial conditions and model parameters for the runs performed here are from ECCOv4r3. The least squares problem solved by the ECCO model uses the method of Lagrange multipliers through iterative improvement, which relies upon a quasi-Newton gradient search (*Noce dal*, 1980; *Gilbert and Lemarechal*, 1989). Algorithmic (or automatic) differentiation tools (*Griewank*, 1992; *Giering and Kaminski*, 1998) have allowed for the practical use of Lagrange multipliers in a time-varying non-linear inverse problem such as ocean modeling, eliminating the need for discretized adjoint equations to be explicitly hand-coded. Contributions of observations to the model-data misfit function are weighted by best-available estimated data and model representation error variance (*Wunsch and Heimbach*, 2007). The observational data assimilated into the ECCO state estimate are discussed in *Forget et al.* (2015a) and *Fukumori et al.* (2017). These data include satellite-derived ocean bottom pressures, sea ice concentrations, sea surface temperatures, sea surface salinities, sea surface height anomalies, and mean dynamic topography, as well as profiler- and mooring-derived temperatures and salinities (*Fukumori et al.*, 2017). No ocean mixing parameter or biogeochemical tracer data are assimilated during the ECCO optimization. The control variables that are inverted and optimized for by ECCO include the initial condition of the sea surface heights, ocean velocities, temperatures, and salinities; time-mean three-dimensional distribution of Redi coefficients (*Redi*, 1982), Gent-McWilliams coefficients (*Gent and McWilliams*, 1990), and κ_ρ (*Gaspar et al.*, 1990); and time-varying two-dimensional surface forcing fields. Fifty-nine iterations in the optimization run of ECCO were performed to arrive at the ECCOv4r3 solution we start from for our adjoint sensitivity experiments. The resulting κ_ρ field in the ECCOv4r3 solution will be referred to as $\kappa_{\rho,ECCO}$ hereafter. While we are presenting some shortcomings of the ECCO framework in terms of κ_ρ here, sequential data assimilation systems also have problems with κ_ρ , as shown in the Appendix.

We run ECCO in two configurations: 1) a “re-run,” where all control variables are set to be their estimated values from ECCOv4r3 in forward mode, and 2) an “adjoint sensitivity” run of the optimized state estimate in forward plus adjoint modes, where data are included in the cost function but not technically “assimilated” because the model input parameters do not change. An adjoint sensitivity is essentially the sensitivity of one variable to another, computed by making use of the model’s adjoint. Formally, an adjoint sensitivity is $\partial J / \partial X$, where the cost function J is a sum of weighted misfits to observations and a control variable X is a variable that the model estimates by making use of its adjoint and observations—see Section 2.2.1.1. The adjoint sensitivities provide information about which directions the model should change X in order to minimize J . (*Masuda and Osafune*, 2021) showed some examples of adjoint sensitivities of several model parameters in their ocean state estimate to a vertical mixing parameter (slightly different from κ_ρ). We also compute adjoint sensitivities in the present study, but using ECCO with respect to $X = \kappa_\rho$.

In order to simulate oxygen and phosphate concentrations, several tracers are carried using Biogeochemistry with Light, Iron, Nutrients and Gases (BLING) model (*Galbraith et al.*, 2015). BLING is an intermediate complexity biogeochemistry model

190 that uses several prognostic tracers and parameterized, implicit representations of iron, macronutrients, and light limitation and photoadaptation. BLING has been shown to compare well with the Geophysical Fluid Dynamics Laboratory’s full-complexity biogeochemical model, TOPAZ (*Galbraith et al.*, 2015), and has been adapted for use in the MITgcm with its adjoint (*Verdy and Mazloff*, 2017).

The following is a summary of the ECCO experiments we run (Table 2):

- 195 – **E-CTRL** - a forward ECCOv4 simulation that uses the parameters from ECCOv4r3; this simulation can be referred to as a “re-run”
- E_{κ} - an adjoint sensitivity (with respect to $X = \kappa_{\rho}$) experiment in which only the base-10 logarithm of the $\kappa_{\rho, W15}$ and $\kappa_{\rho, K17}$ products are included in the misfit function J
- E_O - an adjoint sensitivity (with respect to $X = \kappa_{\rho}$) experiment in which only oxygen concentrations from the World Ocean Atlas (2013) climatology are included in the misfit function J
- 200 – E_{ϵ} - an adjoint sensitivity (with respect to $X = \epsilon$) experiment in which only the base-10 logarithm of the $\epsilon_{W15} = \kappa_{\rho, W15} N^2 / 0.2$ and $\epsilon_{K17} = \kappa_{\rho, K17} N^2 / 0.2$ products are included in the misfit function J , where the stratification N^2 is from the World Ocean Atlas (2013) climatology

Note that the initial guess for $\kappa_{\rho, ECCO}$ is $10^{-5} \text{ m}^2 \text{ s}^{-1}$ and in the absence of observation-driven adjustments, $\kappa_{\rho, ECCO}$ remains at or is close to its initial value. Lastly, we analyze the adjoint sensitivities with dissipation rates in the cost function (E_{ϵ} in 205 Table 2.2) in order to assess whether the stratification—a multiplying factor between κ_{ρ} and the dissipation rates according to *Osborn* (1980)—provides information about κ_{ρ} .

We take the ECCOv4r3 solution as initial conditions and, with the exception of E-CTRL, we perform an adjoint calculation for each of the experiments. The adjoint sensitivities are accumulated and averaged over the full integration period. Only one year was run for each of the adjoint simulations because we are using time-invariant climatologies, and one year suffices to 210 demonstrate the point that the assimilation of a biogeochemical tracer may reduce the bias in κ_{ρ} . Our results are not qualitatively sensitive to the run length. The adjoint sensitivities from E_{κ} are not sensitive to their run length due to the lack of time-dependence of κ_{ρ} , but are sensitive to their initial conditions as determined by the ECCOv4r3 solution.

We begin E_O from a previously-derived product that has been spun-up from an initial climatology (*Dutkiewicz et al.*, 2005) because observations do not exist for every grid cell and beginning from this product minimizes model drift. If we 215 were to start from different initial conditions, the model’s drift would confound the interpretation of our adjoint sensitivities. The depth-averaged differences between the uninterpolated World Ocean Atlas (2013) product and the initial conditions for oxygen concentrations in our ECCO run using BLING are shown in Fig. 2. The differences are largest in the Arctic Ocean, northeastern Pacific Ocean, and near the coasts, particularly on the eastern side of the American continent, the southwestern side of the African continent, around the Kuroshio/Sea of Japan region, along almost every coastline of Oceania, and in the 220 Mediterranean Sea (Fig. 2a). These differences are likely due to the deficiencies in model resolution, the sparse observations in regions such as the Arctic Ocean, the locations of sea ice (*Bigdeli et al.*, 2017), and the parameterization of the tracer air-sea

fluxes (e.g., *Atamanchuk et al.* (2020)). We need to consider the spatial patterns shown in Fig. 2 when interpreting the signs of the adjoint sensitivities.

2.2.2 ECCO adjoint sensitivity analyses

225 In order to understand whether κ_ρ could be estimated more accurately through data assimilation of oxygen concentrations, we need to further explain the details of our adjoint sensitivity experiments with ECCO. We define the objective (or cost) function here to more formally explain what the adjoint sensitivity is. ECCO calculates the cost function to be minimized, J , as (*Stammer et al.*, 2002):

$$J = \sum_{t=1}^{t_f} [\mathbf{y}(t) - \mathbf{S}\tilde{\mathbf{x}}(t)]^T \mathbf{W}(t) [\mathbf{y}(t) - \mathbf{S}\tilde{\mathbf{x}}(t)] \quad (1)$$

230 where t_f is the final time step, $\tilde{\mathbf{x}}$ is the model-based estimate of the state vector \mathbf{x} , \mathbf{S} is the observation matrix that relates the model state vector to observed variables (such that $\mathbf{S}\tilde{\mathbf{x}}$ is the model-based estimate of the observables \mathbf{y}), and \mathbf{W} is the weight (inverse square of the uncertainty) of the observations. In each of our adjoint sensitivity experiments, the data vector \mathbf{y} only contains the data set specific to the experiment (see Table 2.2) so we emphasize here that J is different for each of our experiments. The uncertainties in $\kappa_{\rho,ECCO}$ in E_κ are set to be three times the values of the observationally-derived κ_ρ because
 235 of the level of agreement between the $\kappa_{\rho,W15}$ and $\kappa_{\rho,micro}$ (*Whalen et al.*, 2015). The uncertainties in oxygen concentrations in E_O are set to be 2% of the values of the measured dissolved oxygen concentrations because those are the measurement errors associated with most instruments.

The adjoint sensitivities computed in this study are the derivatives of J in Eq. 1 with respect to κ_ρ . While the adjoint sensitivities of J to the controls space in experiment E_O must be computed online, those in E_κ can either be computed online
 240 or offline using an analytical equation (see below). The adjoint sensitivity run with κ_ρ included in the misfit calculation of experiment E_κ can be calculated offline using output from the E-CTRL run instead of being calculated online as follows:

$$\frac{\partial J}{\partial X} = -2 \frac{(X_{obs} - X_{model})}{\sigma_X^2}. \quad (2)$$

Here, $X = \kappa_\rho$ is the control variable, $\mathbf{y} = X_{obs}$ is the observationally-derived value of X described in the previous section, $X_{model} = \mathbf{S}\tilde{\mathbf{x}}$ is the value that ECCO estimates for X , and σ_X^2 (entries of \mathbf{W}) is taken to be $3X_{obs}$ (or the base-10 logarithm
 245 of this in the case of κ_ρ) due to the factor of 2-3 uncertainty. The offline Eq. 2 and online sensitivities have been verified to be in agreement. For X_{model} , we use the offline values calculated from the E-CTRL run following Eq. 2.

Short of assimilating a particular data set (e.g., dissolved oxygen concentrations) in a new optimization run of ECCO, we assess whether the assimilation of a particular data set could lead to a more accurate estimate of a control variable that can be observed (e.g., κ_ρ). Because the observations of κ_ρ here are not direct measurements, we first need to show that observationally-
 250 derived κ_ρ has a smaller bias with respect to independent observations than the model's estimate of κ_ρ . We devote the first portion of our study to determining whether $|\kappa_{\rho,W15} - \kappa_{\rho,micro}| < |\kappa_{\rho,ECCO} - \kappa_{\rho,micro}|$ (and, by extension, $\kappa_{\rho,K17}$ in place of $\kappa_{\rho,W15}$) is true. We do this because $\kappa_{\rho,micro}$ is limited in its spatial coverage compared to $\kappa_{\rho,W15}$. However, we don't want to assimilate $\kappa_{\rho,W15}$ (or $\kappa_{\rho,K17}$) because of their observational uncertainties and still limited spatial coverage relative to

dissolved oxygen concentrations. The data product with higher accuracy (dissolved oxygen concentrations) will have larger weights (\mathbf{W} in Eq. 1) and thus will exert more influence in constraining $\kappa_{\rho,ECCO}$ —bringing it closer to microstructure values. So if we can show that the adjustments to κ_{ρ} in ECCO are similar, whether we provide information from observationally-derived κ_{ρ} or a directly measured tracer (dissolved oxygen concentrations), then we would assimilate the tracer. The problem with doing a direct comparison of the adjustments is that the uncertainties in observationally-derived κ_{ρ} products are large. The significance of the correlations between the adjoint sensitivities in E_{κ} and E_O are difficult to determine with such large uncertainties. Thus, we first quantify the extent to which the adjoint sensitivities from two runs (here, E_{κ} and E_O) have the same sign. Specifically, we inspect whether $\partial J/\partial \kappa_{\rho}$ has the same sign in E_{κ} and E_O where $|\kappa_{\rho,W15} - \kappa_{\rho,ECCO}|$ is significantly different from zero (i.e., $\kappa_{\rho,W15}$ is more than a factor of three greater or less than a factor of three smaller than $\kappa_{\rho,ECCO}$). We perform these comparisons in regions where the difference between the observationally-derived κ_{ρ} products and $\kappa_{\rho,ECCO}$ exceeds three times the observational products' magnitudes (i.e., statistically distinguishable from zero). In the same regions, we then calculate the correlations between the adjoint sensitivities from E_{κ} and E_O . Because model errors unrelated to κ_{ρ} can confound these correlations, we additionally look at regions where the difference between oxygen concentrations from the model and the World Ocean Atlas (2013) is relatively small to determine whether oxygen concentrations guide the state estimate's control space to improve the magnitude of κ_{ρ} .

3 Results

In this study, our first goals are to quantify the biases between κ_{ρ} from ECCO and κ_{ρ} from observations. Then we analyze results from two adjoint sensitivity runs: one with misfits to observed κ_{ρ} derived from the finescale parameterization and the other with misfits to observed O_2 . We use these results to investigate the potential to use O_2 as a constraint for improving $\kappa_{\rho,ECCO}$ in a future optimization.

3.1 Model-inverted vs microstructure-inferred κ_{ρ} comparisons

Here, we compare the average $\kappa_{\rho,micro}$ profile that is comprised of 24 campaigns' worth of data (*Waterhouse et al.*, 2014) (see their Fig. 6; black curve in Fig. 3) with the average $\kappa_{\rho,ECCO}$ profiles and the $\kappa_{\rho,W15}$ product. A geometric average is taken for each profile because this is more representative than an arithmetic average for a small sample size and when the data are not normally distributed (*Manikandan*, 2011), like the log-normal distribution of κ_{ρ} .

The average κ_{ρ} profile in the first iteration of ECCO's optimization—i.e., the initial guess of $\kappa_{\rho,ECCO}$ —is typically smaller than the microstructure profile, particularly at 1000 m where the difference is approximately an order of magnitude (Fig. 3). At iteration 59 (which is the ECCOv4r3 solution), the difference between $\kappa_{\rho,ECCO}$ and $\kappa_{\rho,micro}$ decreases. However, agreement between the average profiles of $\kappa_{\rho,ECCO}$ and $\kappa_{\rho,micro}$ is still worse than the agreement between $\kappa_{\rho,W15}$ and $\kappa_{\rho,micro}$. The agreement between $\kappa_{rho,W15}$ and $\kappa_{\rho,micro}$ at each of the three depth bins is well within a factor of three (not shown here).

3.2 Model-inverted vs finescale parameterization-derived κ_ρ comparisons

285 We next show $\kappa_{\rho,W15}$ and differences between $\kappa_{\rho,W15}$ and $\kappa_{\rho,ECCO}$ because this highlights the spatial patterns of the adjoint sensitivities in E_κ (see later). The ratio between the $\kappa_{\rho,W15}$ product (Figs. 4a,c,e) and $\kappa_{\rho,ECCO}$ varies throughout the globe (Figs. 4b,d,f). The percent of volume where $\kappa_{\rho,ECCO}$ is at least an order of magnitude different from $\kappa_{\rho,W15}$ is 43.8%. The values of $\kappa_{\rho,ECCO}$ are smaller than those in the observational product in the Kursoshio Extension (500-1000 meters depth), subpolar North Atlantic (500-1000 meters depth), Southern Ocean, equatorial regions in the Atlantic, and shallow (250-500
290 meters depth) Indian and eastern Pacific Oceans (Figs. 4b,d,f). The $\kappa_{\rho,ECCO}$ field is comparatively large in the model's near-equatorial regions, where the intermittency of strong mixing events is likely not captured—even in a time-mean sense—by a time-invariant $\kappa_{\rho,ECCO}$. However, the fidelity of $\kappa_{\rho,W15}$ supplemented with $\kappa_{\rho,K17}$ is unknown near the equator. The fact that $\kappa_{\rho,ECCO}$ and $\kappa_{\rho,W15}$ disagree within the deep mixed layers at high latitudes is not consequential for tracer transport. The errors in $\kappa_{\rho,ECCO}$ could be partially compensating for errors in the vertical component of the along-isopycnal diffusivity
295 tensor and/or numerical diffusion.

The incomplete historical observations of temperature, salinity, and pressure are not sufficient to constrain $\kappa_{\rho,ECCO}$. Values of $\kappa_{\rho,ECCO}$ do not agree well with the observationally-derived κ_ρ ($\kappa_{\rho,micro}$ and $\kappa_{\rho,W15}$), possibly for this reason. While there is an abundance of Argo data in the upper 2000 meters, these data are insufficient to constrain the $\kappa_{\rho,ECCO}$ in a realistic manner. The sparsity of the observations below 2000 meters depth, in high latitude regions, and in some near-coastal areas—
300 where internal wave-induced mixing can be important—is relevant because complete observational coverage of the ocean's temperature, salinity, and pressure could, in principle, better constrain κ_ρ using inverse modeling (Groeskamp et al., 2017). However, the lack of time-dependence of $\kappa_{\rho,ECCO}$, the presence of numerical mixing, and joint estimation of many under-determined parameters in ECCO could also lead to erroneous $\kappa_{\rho,ECCO}$.

3.3 Adjoint sensitivities in ECCO

305 Because the data that get assimilated into ECCO are insufficient to constrain $\kappa_{\rho,ECCO}$ well enough to match $\kappa_{\rho,W15}$ or $\kappa_{\rho,micro}$, assimilating additional variables controlled by mixing may assist in further improving the modeled mixing parameters. Oxygen is a prime candidate since its distribution is, in part, determined by the local κ_ρ . To test this, we run multiple adjoint sensitivity experiments in which either observationally-derived κ_ρ or oxygen is included in the misfit calculation to guide constraints on κ_ρ .

310 We now show the adjoint sensitivity calculations using Eq. 2 for κ_ρ misfits (experiment E_κ in Table 2.2) in Fig. 5; these are later compared with the sensitivities for oxygen concentration misfits in experiment E_O . A positive adjoint sensitivity implies that the misfit can be reduced by decreasing $\kappa_{\rho,ECCO}$. The signs of $\partial J / \partial \kappa_\rho$ (Fig. 5a) are consistent with the signs of disagreement shown in Fig. 4b,e,h, by construction, and with the disagreements with microstructure shown in Fig. 3. Because $\kappa_{\rho,ECCO}$ tends to be very large inside mixed layers, $\partial J / \partial \kappa_\rho$ tends to be positive and larger at many locations in the subpolar
315 latitudes where there are deep mixed layers in the model but possibly not in the real ocean; conversely, $\partial J / \partial \kappa_\rho$ can be negative where the mixed layer depth is too shallow in ECCO, but this isn't the only reason for $\partial J / \partial \kappa_\rho < 0$. The large positive values

of $\partial J/\partial \kappa_\rho$ within the mixed layer and some other regions overwhelms the zonal averages in favor of positive values (Fig. 5c). $\kappa_{\rho,ECCO}$ needs to be decreased in many regions at depths shallower than 500 meters to agree better with $\kappa_{\rho,W15}$ and $\kappa_{\rho,K17}$ (red regions in Figs. 4b,d,f), but microstructure measurements (X's in Figs. 4b,d,f) were often taken in locations where $\kappa_{\rho,ECCO}$ should be increased (blue regions in Figs. 4b,d,f) or stay the same. These are regions where there are prominent topographic features and where the centers of subtropical gyres are found.

We next compare $\partial J/\partial \kappa_\rho$ from E_κ with $\partial J/\partial \kappa_\rho$ from E_O . In E_O , $\partial J/\partial \kappa_\rho$ is generally negative in subtropical regions (Figs. 5b,d). Overall, the locations of the positive/negative signs of $\partial J/\partial \kappa_\rho$ are not the same everywhere between the E_κ and the E_O experiments, but they agree in many regions (Figs. 5a,c and Figs. 5b,d), which account for nearly two-thirds (three-fourths) of the ocean's volume where they can be compared (in the subtropics, between 20°-50°N/S, non-white regions in Fig. 6; Table 4). The ocean basin with the highest percent volume of agreement in adjoint sensitivity signs between E_κ and E_O is the subtropical North Atlantic Ocean, with nearly 85% volume agreement. The subtropical South Atlantic Ocean is the only subtropical basin with less than half of its volume in agreement in adjoint sensitivity sign. In general, the tropical regions (between 20°S and 20°N) have adjoint sensitivity signs in lesser agreement than the subtropical regions and the subpolar regions (poleward of 50°N/S) are the regions with the lowest percent volume agreements in adjoint sensitivity signs.

Even with general agreement in signs of sensitivities between E_κ and E_O , we need to address whether this agreement is random—as their correlation is due to the large uncertainties in $\kappa_{\rho,W15}$ and $\kappa_{\rho,K17}$ —or underpinned by physical reasons. We first focus on the locations with detectable errors in $\kappa_{\rho,ECCO}$. The regions where the signs of $\partial J/\partial \kappa_\rho$ agree from the two experiments (Figs. 6) and have large differences between $\kappa_{\rho,ECCO}$ and the combined $\kappa_{\rho,W15}$ and $\kappa_{\rho,K17}$ product, tend to have relatively small oxygen concentration misfits (Fig. 2). For example, when only regions with less than one standard deviations above the average oxygen concentration misfits are selected, the signs of the adjoint sensitivities agree between E_O and E_κ over 60.8% of the volume with sufficient data. However, the larger the oxygen concentration misfits, the more often the signs of the sensitivities agree. When only regions with more than three standard deviations above the average oxygen concentration misfits are selected, the signs of the sensitivities always agree (yellow regions in Fig. 6). Given the good agreement in signs of the sensitivities in regions with large κ_ρ misfits, we next inspect the sensitivity sign patterns in regions with small κ_ρ misfits.

The vast majority of the locations where disagreements occur in sensitivity signs are in places with statistically indistinguishable differences between $\kappa_{\rho,ECCO}$ and $\kappa_{\rho,W15}$ supplemented with $\kappa_{\rho,K17}$ (white regions in Fig. 6 that are non-white in Fig. 5). The regions with statistically indistinguishable differences in κ_ρ account for 56.2% of the volume of the ocean where the adjoint sensitivities from E_O and E_κ can be compared. Within these regions, there are differences in the signs of the sensitivities in locations where κ_ρ is not expected to dominate the variability in oxygen. These regions include, for example, the equatorial Pacific and Atlantic Oceans, where *Palter and Trossman (2018)* and *Brandt et al. (2021)* point out that ocean circulation changes significantly influence long-term changes in oxygen. Another example is in the open subpolar North Atlantic Ocean (the blue region in the Labrador Sea in Fig. 6a), where *Atamanchuk et al. (2020)* present observational evidence that air-sea fluxes mediated by bubble injection—not represented by ECCO—dominate the variability in oxygen down to 1000 meters depth. When these tropical and subpolar regions (outside of the 20° – 50°N/S bands) are excluded, the percent volume of the ocean where the signs of the adjoint sensitivities agree between E_κ and E_O increases. Given that there are known phys-

ical processes not dominated by κ_ρ causing variations in oxygen concentrations in regions outside of the (sub)tropics where there are statistically insignificant differences between $\kappa_{\rho,ECCO}$ and the observationally-derived κ_ρ , our interpretation of the patterns shown in Figs. 5 and 6 is that κ_ρ controls much of the variability in oxygen concentrations in the (sub)tropical regions. This is one indication that dissolved oxygen concentrations could provide information about κ_ρ .

We further address whether the potential information dissolved oxygen concentrations provide about κ_ρ is due to the information oxygen contains about stratification. We do this by using the adjoint sensitivity results obtained from experiment E_ϵ with observationally-derived dissipation rates, $\epsilon = N^2\kappa_\rho/0.2$ —where N^2 is the stratification—instead of κ_ρ , in the misfit function via Eq (2) and multiply the adjoint sensitivity of E_O by $0.2/N^2$ so that their sensitivities are each taken with respect to ϵ (parentheses in Table 4). We find approximately equal agreement between the signs of the adjoint sensitivities from E_O (scaled by $0.2/N^2$) and E_ϵ as we do between those from E_O and E_κ in every region. Because ϵ is related to κ_ρ through the stratification, we suggest that the information oxygen concentrations provide about κ_ρ is likely independent of the stratification field.

Lastly, in order to examine whether there is a statistically significant relationship between the adjoint sensitivities from E_κ and E_O . We again focus on the regions where the difference between $\kappa_{\rho,ECCO}$ and observational κ_ρ products (from Argo and microstructure) is statistically significant (greater than a factor of three), but also filter out the adjoint sensitivities where the differences between oxygen concentrations from ECCO and those from the World Ocean Atlas (2013) are statistically significant. The correlations tend to be small but positive (Fig. 7). However, if we perform Monte Carlo simulations where we sample κ_ρ values within its uncertainty and recompute the adjoint sensitivity for E_κ and then its correlation with that for E_O , the maximum correlations we find are larger, particularly where the adjoint sensitivities are both negative (Figs. 7a,c). This suggests that $\kappa_{\rho,ECCO}$ may be at least partially constrained by the information provided by oxygen concentrations. That is, oxygen concentrations inform adjoint sensitivities that typically direct $\kappa_{\rho,ECCO}$ to improve relative to observationally-derived κ_ρ . Constraints that the assimilation of oxygen concentrations may have on $\kappa_{\rho,ECCO}$ may be beneficial, but not a perfect substitute for the assimilation of accurately measured κ_ρ itself.

4 Discussion and Concluding Remarks

4.1 Discussion

This study evaluated the potential to improve the diapycnal diffusivities (κ_ρ) in the ECCOv4 ocean parameter and state estimation framework. We assessed the fidelity of the inverted field of $\kappa_{\rho,ECCO}$ by first comparing the average observed vertical profiles of $\kappa_{\rho,ECCO}$ with those inferred from microstructure. The comparison was not favorable. $\kappa_{\rho,ECCO}$ is inverted for within the ECCO framework through constraints of vertical profiles of temperature and salinity—e.g., from Argo profiles. The low fidelity suggests that these hydrographic data alone are not sufficient to constrain $\kappa_{\rho,ECCO}$, but there may be some model errors that would lead to errors in $\kappa_{\rho,ECCO}$ even in the presence of globally complete hydrographic observations (see Section 4.2).

We then investigated which additional observations can be used as new constraints to improve the fidelity of the inverted
385 $\kappa_{\rho,ECCO}$. The products we used were observationally-derived κ_{ρ} based on Argo (the W15 product) and ship-based CTD (the
K17 product) hydrographic data and oxygen concentration (WOA, 2013). To justify the use of the observationally-derived κ_{ρ}
products, we also evaluated them by comparing them with the microstructure-inferred product. $\kappa_{\rho,W15}$ and $\kappa_{\rho,W17}$ have better
agreement with the microstructure-inferred data than $\kappa_{\rho,ECCO}$ does.

We inspected the misfit of the model parameter $\kappa_{\rho,ECCO}$ with respect to $\kappa_{\rho,W15}$ and $\kappa_{\rho,K17}$ and motivated use of dissolved
390 oxygen concentration data as a potential constraint in ECCO. One drawback of the observationally-derived data products
for κ_{ρ} is that they have large uncertainties (here, approximated by a factor of three). Observed oxygen concentrations, on
the other hand, has smaller relatively uncertainty. More importantly, we showed that vertical oxygen gradients have similar
geographical patterns to energy dissipation rates. We therefore performed an additional adjoint sensitivity experiment with
oxygen concentration data as the only data in the misfit function. Adjoint sensitivities results were compared between the
395 experiment with measured oxygen in the misfit function and observationally-derived κ_{ρ} in the misfit function. Regions where
the sensitivities agree in signs between the two experiments are locations where we believe adjustments in κ_{ρ} , as informed by
these data, can help improve $\kappa_{\rho,ECCO}$. These regions include nearly three-quarters of the volume of comparable seawater in the
subtropics. Correlations between adjoint sensitivities from each experiment are positive where differences between the oxygen
concentrations in the model and observations are relatively small. These findings suggest that dissolved oxygen concentrations
400 could be used to more accurately estimate κ_{ρ} in a newly optimized ECCO solution. However, given the magnitudes of the
correlations between the adjoint sensitivities, assimilation of observationally-derived κ_{ρ} could (additionally) be necessary,
especially if their uncertainties are better quantified.

4.2 Caveats and future directions

Many factors—including a significant absence of independent observations for assessment, a combination of measurement and
405 structural errors, numerical diffusion in our simulations, and unconstrained parameters in the biogeochemical modules—have
stymied progress in state estimation of ocean mixing parameters. First, only one ocean mixing parameter—namely, κ_{ρ} —has been
compared with independent observational data—specifically, microstructure. This is the primary reason why we focused on κ_{ρ}
in our study. Second, the ECCO-estimated κ_{ρ} accounts for other model errors (e.g., structural ones suggested by Polzin *et al.*
(2014)), which explains some of the model biases relative to microstructure observations. For instance, the ECCO-estimated κ_{ρ}
410 should be time-dependent as well as spatially-varying, but it is only spatially-varying. In the presence of other estimated model
parameters and initial conditions, some parameters could be compensating for errors in κ_{ρ} . Additionally, there is numerical
diffusion in the model, which could confound some physical inferences about the model (e.g., regarding how sensitive the
model's state is to κ_{ρ} relative to along-isopycnal diffusion). Numerical errors could remain and result in the primary source
of error in the ocean state estimate if sufficient constraints are placed on κ_{ρ} in ECCO. Lastly, there are several unconstrained
415 parameters in biogeochemical modules used to calculate biogeochemical tracers (Verdy and Mazloff, 2017), so some of the
disagreements in signs of the adjoint sensitivities found here could be associated with other inaccurate parameters.

These challenges can continue to be overcome by allowing models and observations to inform each other. First, the observationally-derived κ_ρ from the finescale parameterization could be further scrutinized using ship-based CTD data taken concurrently with microstructure velocity shear data. A preliminary analysis suggests that the percent difference between the full depth-averaged microstructure CTD-derived κ_ρ from the finescale parameterization and the microstructure-inferred κ_ρ is indistinguishable from zero (1.68%), but the quality of the the microstructure CTD data has not been fully assessed. Second, we would need to account for the time-dependence of κ_ρ in a future ocean state estimate. The under-determined nature of the parameter estimation procedure makes this difficult. These efforts would also benefit from minimizing spurious mixing due to numerical diffusion (e.g., *Holmes et al. (2021)*) through choosing a different advection scheme, but this would add computational expense.

The effective proxy potential framework of *Loose and Heimbach (2021)* could be used to indicate whether measurements of oxygen concentrations in particular locations are more informative of κ_ρ than in other locations. We did not pursue this in the present study because our adjoint runs use a global misfit; if we perform an ensemble of adjoint sensitivity runs with a single observation in each run, then we could calculate the effective proxy potential at each of these observation locations. Third, unconstrained parameters in the biogeochemical modules could potentially be circumvented. One potential way to do this is by assimilating preformed oxygen (i.e., oxygen without any biological influence, making it a passive tracer) instead of oxygen concentrations. Observationally-derived transit-time distributions with a maximum entropy-based method from previous studies (e.g., *Khaliwala et al. (2009)*; *Zanna et al. (2019)*) or from a tracer-informed ocean state estimate (*DeVries and Holzer, 2019*) can help derive preformed oxygen from oxygen concentration observations. Lastly, the (imperfectly-known) initial conditions of each biogeochemical tracer will also need to be included in the input control vector during optimization of the ocean state estimate. Our results suggest that the assimilation of biogeochemical tracers will help build a more complete representation and understanding of κ_ρ , and the next step is to perform another optimization of the ocean state estimate including these tracer observations.

Appendix A: Model with a sequential data assimilation framework

A1 GEOS-5 and the GMAO S2S Ocean Analysis

440 To demonstrate a problem with κ_ρ in a sequential data assimilation framework, we present example output from a reanalysis product and output from an identical ocean model hindcast without any data assimilation. GEOS-5 includes a global, finite volume atmospheric general circulation model that is used for numerical weather prediction, seasonal-to-decadal forecasts, and as the background field for atmospheric reanalyses (Molod *et al.*, 2015). The ocean is represented by the GFDL Modular Ocean Model (Griffies *et al.*, 2015), version 5 (MOM5) and the Los Alamos Community Ice CodE sea ice model (Hunke *et al.*,
445 2013), version 4.1 (CICE4.1). We use a configuration of the GEOS-5 modeling system with a 1° (0.5° at equator) resolution on a tripolar (Murray, 1996) staggered Arakawa B-grid (Mesinger and Arakawa, 1976) and 50 geopotential levels for MOM5, 2° resolution and 24 pressure levels for the atmospheric model, and 1° resolution and 3 layers for CICE4.1. Historical aerosols (sulfate, dust, and sea salt) and biomass burning emissions (black and organic carbon) updated from the Goddard Chemistry Aerosol Radiation and Transport (GOCART) model (Chin *et al.*, 2002) are used over the time period 1992 through 2016. Initial
450 conditions are based on a long spin-up that used MOM4 coupled to one version of the GEOS-5 atmosphere model (Molod *et al.*, 2012) and hundreds of additional years of spin-up that used MOM4 coupled to a slightly different version of the GEOS-5 atmosphere model. The differences between the two versions of the GEOS-5 atmospheric model used in the two phases of spin-up include developments in cloud microphysics and atmospheric chemistry.

κ_ρ , Redi coefficients, and Gent-McWilliams coefficients are determined in MOM5 as follows. κ_ρ in MOM5— $\kappa_{\rho,GEOS5}$
455 hereafter—is represented by the K-Profile Parameterization (KPP; Large *et al.*, 1994) and a parameterization for mixing due to internal tides (Simmons *et al.*, 2004). Shear-driven mixing, gravitational instabilities that can cause vertical convection, and double-diffusive processes, which can cause the temperature diffusivity to be different from the salinity diffusivity, are accounted for in the interior (Large *et al.*, 1994). The resulting $\kappa_{\rho,GEOS5}$ field spatio-temporally varies. However, this combination of parameterizations does not make use of an explicit energy budget that accounts for conversion between kinetic and
460 potential energy when determining $\kappa_{\rho,GEOS5}$. The Redi coefficients (Redi, 1982) and Gent-McWilliams coefficients of the (Gent and McWilliams, 1990) parameterization for mesoscale eddies are, by default, prescribed to be $600 \text{ m}^2 \text{ s}^{-1}$ everywhere, except for some variation in western boundary current regions for the Gent-McWilliams coefficients. The Redi coefficients and Gent-McWilliams coefficients are, thus, constant in time and in most locations. A mixed layer instability scheme for the submesoscale transport by (Fox-Kemper *et al.*, 2011) is used.

465 We use a reanalysis product, which uses the same underlying modeling system as the GEOS-5 coupled earth system model, called the Global Modeling and Assimilation Office sub-seasonal to seasonal (GMAO S2S) Ocean Analysis. The output of the GMAO S2S Ocean Analysis highlights how κ_ρ can behave due to the disruption of dynamical balance that can be the result of the use of a sequential data assimilation system (Stammer *et al.*, 2016; Pilo *et al.*, 2018). The GMAO S2S Ocean Analysis only assimilates hydrographic information to constrain κ_ρ and relies on the same parameterizations as GEOS-5's ocean component
470 to calculate κ_ρ .

The NASA GMAO has recently updated their GEOS-5 sub-seasonal to seasonal forecast system (S2S-v2.1; https://gmao.gsfc.nasa.gov/cgi-bin/products/climateforecasts/geos5/S2S_2/index.cgi). This new system is the current contribution of the GMAO to the North American Multi-Model project (<http://www.cpc.ncep.noaa.gov/products/NMME/about.html>) and NOAA's experimental sub-seasonal ensemble project (<http://cola.gmu.edu/kpegon/subx/index.html>). A configuration of the modeling system is used that is nominally 0.5° resolution on a tripolar (Murray, 1996) staggered Arakawa B-grid (Mesinger and Arakawa, 1976) and 40 geopotential levels for MOM5, and 0.5° resolution and 5 layers for CICE4.1 with atmospheric forcing from MERRA-2 (Modern-Era Retrospective analysis for Research and Applications, Version 2) reanalysis (Gelaro *et al.*, 2017). The GMAO S2S Ocean Analysis (Molod *et al.*, 2020) is a reanalysis product that uses a system similar to the Local Ensemble Transform Kalman Filter (LETKF) data assimilation procedure described by (Penny *et al.*, 2013), but where the background error is calculated offline using ensemble members of freely coupled simulations. The background error does not explicitly account for uncertainties in the ocean mixing parameters, as it is only a function of the observed and background temperatures and salinities. The temperature and salinity would change and so would the calculated covariances if the mixing parameterizations were changed, but each of the 21 background free-running simulations have the same mixing parameterization, as they only differ in their initialization.

The following datasets were used by the GMAO S2S data assimilation modeling system. A relaxation procedure, or update, is applied towards the MERRA-2 sea surface temperatures and sea ice fraction from the NASA TEAM-2 product (Markus *et al.*, 2009) at a 5-day assimilation cycle. No ocean mixing parameter data are assimilated. Assimilated in situ observational data that provide temperatures and salinities come from TAO, PIRATA, RAMA, XBT, CTD, and Argo instruments. Satellite altimetry data that provide sea level anomalies come from TOPEX, ERS-1+2, Geosat FO, Jason-1, Jason-2, Jason-3, Envisat, Cryosat-2, Saral, HY-2A, and Sentinel 3A. The absolute dynamic topography is calculated as the sum of the sea level anomaly and the mean dynamic topography, which is estimated using GOCE and GRACE data, all available altimetry, and in situ data. Absolute dynamic topography data are assimilated into the model system using the same method as for the in situ data, except these data are thinned along-track and a Gaussian weighted mean using a decorrelation scale of 1000 km is calculated prior to assimilation. In addition, the global trend was removed from the absolute dynamic topography before assimilation and zero net input of water was applied. Precipitation is corrected using the Global Precipitation Climatology Project version 2.1 (GPCPv2.1, provided by the NASA/Goddard Space Flight Center's Laboratory for Atmospheres, which calculates the dataset as a contribution to the GEWEX Global Precipitation Climatology Project) and Climate Prediction Center (CPC) Merged Analysis of Precipitation (CMAP, provided by the NOAA/OAR/ESRL PSD, Boulder, Colorado, USA, from their website at <http://www.esrl.noaa.gov/psd/>), as described by (Reichle *et al.*, 2011) except for MERRA-2 instead of MERRA data. All other atmospheric forcing fields used in the construction of the reanalysis came from MERRA-2. The GMAO S2S modeling system is an update to the one described in (Borovikov *et al.*, 2017). As such, the model only ran for the period: May of 2012 to March of 2019.

A2 Steric sea level budget framework

In order to examine whether the analysis increments can dynamically impact κ_ρ , we analyze a model's buoyancy budget, which is broken down into heat and salt budgets and used to calculate the steric sea level budget. The tracer tendency equation terms required for the heat and salt budgets were computed online and saved as the reanalysis was running. The tracer equations can be broken down into individual contributions (Palter *et al.*, 2014),

$$\begin{aligned}\rho \frac{d\Theta}{dt} + \rho A^\Theta &= -\nabla \cdot \mathbf{J}^\Theta + \rho Q^\Theta \\ \rho \frac{dS}{dt} + \rho A^S &= -\nabla \cdot \mathbf{J}^S + \rho Q^S,\end{aligned}\tag{A1}$$

where $d/dt = \partial/\partial t + (\mathbf{v} + \mathbf{v}^*) \cdot \nabla$ is the material derivative, \mathbf{v} is the resolved velocity field, \mathbf{v}^* is the eddy-induced or quasi-Stokes velocity field that represents parameterized motions, Θ is the potential temperature, S is the salinity, ρ is the locally referenced potential density, \mathbf{J}^Θ and \mathbf{J}^S are the parameterized along-isopycnal and diapycnal mixing fluxes associated with potential temperature and salinity, Q^Θ and Q^S are the sums of sources and sinks of potential temperature and salinity, and A^Θ and A^S are the analysis increments for potential temperature and salinity due to the assimilation of data by a sequential filter-based data assimilation ocean modeling system. The analysis increments in a sequential filter-based data assimilation system can obscure the physics.

The heat and salt budget terms summarized by Equation (A1) are computed as follows. The resolved, mesoscale, and submesoscale transports are accounted for in the material derivatives Θ and S , the neutral and diapycnal diffusion of Θ and S are accounted for by \mathbf{J}^Θ and \mathbf{J}^S , and the analysis increments of Θ and S are accounted for by A^Θ and A^S . The neutral diffusion term includes cabbeling, thermobaricity, and a dianeutral contribution that mixes properties by providing for the exponential transition to horizontal diffusion in regions of steep isoneutral slopes according to (Treguier, 1992) and (Ferrari *et al.*, 2008, 2010) where the surface boundary layer is encountered and following (Gerdes *et al.*, 1990) next to solid walls. The diapycnal diffusion term is not added to the vertical component of the along-isopycnal diffusion term, but because of convention (e.g., Palter *et al.*, 2014) is nevertheless referred to as the vertical diffusion term hereafter. The vertical diffusion term also includes penetrating shortwave radiation flux. The sources and sinks of Θ and S accounted for by Q^Θ and Q^S include nonlocal convection (the transport where turbulent fluxes don't depend upon local gradients in Θ or S because buoyant water gets entrained into the mixed layer when the surface buoyancy forcing drives convection above a stratified water column); surface buoyancy fluxes (latent, sensible, shortwave, longwave, and frazil heat fluxes); precipitation minus evaporation; runoff mixing (mixes properties associated with river outflows); downslope mixing (mixes properties downslope to represent the overflow dense waters from marginal seas); sigma-diffusion (mixing properties along terrain-following coordinates in regions with partial bottom cells); numerical smoothing of the free surface (intended to reduce B-grid checkerboard noise); numerical sponge (intended to absorb the Kelvin waves set off by the assimilation of some data); calving of land ice; and frazil ice formation. The runoff mixing, downslope mixing, and sigma-diffusion terms are considered sources or sinks here because they are associated with numerical schemes that aim to resolve problems created by coarse model resolution, the vertical coordinate system used near boundary layers, and imperfect bathymetry. There is no geothermal heating included in the GMAO S2S

Ocean Analysis. The vertical diffusion term includes a subsurface shortwave heating contribution to a function of the κ_ρ field, the mesoscale transport term assumes constant Gent-McWilliams coefficients, and the neutral diffusion term assumes constant Redi coefficients.

At each time step, the model evaluates a tendency term for every process that contributes to (A1) from their parameterized or dynamically calculated values, their units are converted to W m^{-2} and $\text{kg m}^{-2} \text{s}^{-1}$ for Θ and S , and their monthly averages are saved to the output files used in this analysis. Implicit in these output tendency terms is that each term is weighted by the thicknesses of each layer as the model runs and writes the output to file. The heat and salt budget terms saved to file are used to calculate the steric sea level budget as follows. The steric sea level budget terms are computed by scaling the heat tendency terms by α/C_p and the salt tendency terms by -1000β , where C_p (units in $\text{J kg}^{-1} \text{K}^{-1}$) is the specific heat of seawater, $\alpha = -[1/\rho](\partial\rho/\partial T)$ (units in K^{-1}) is the thermal expansion coefficient, and $\beta = [1/\rho](\partial\rho/\partial S)$ (units in kg g^{-1}) is the haline contraction coefficient. In order to get a longitude-latitude map of the terms that depend upon depth shown here, we integrate over depth by summing over the depth dimension. We analyze part of the steric sea level budget of the GMAO S2S Ocean Analysis to examine the relationships between different terms.

Appendix B: Results for the sequential data assimilation framework

B1 Assessments of κ_ρ from models

First, we compare the average $\kappa_{\rho,micro}$ profile that is comprised of 24 campaigns worth of data (Waterhouse *et al.*, 2014) (see their Fig. 6; black curve in Fig. A1a) with the average model-calculated κ_ρ profiles and $\kappa_{\rho,W15}$. A geometric average is taken for each profile because a geometric average is more representative than an arithmetic average for a small sample size and when the data are not normally distributed (Manikandan, 2011), like the log-normal distribution of κ_ρ .

We compare microstructure (black curve in Fig. A1a) with GEOS-5 (red curve in Fig. A1a). $\kappa_{\rho,GEOS5}$, on average, is in close agreement with microstructure over the upper 250-2000 meters. On average, the disagreement with microstructure and Argo is approximately the same as the disagreement between microstructure and GEOS-5. All three κ_ρ are well within the uncertainty of the Argo product. The profiles are also within the temporal variability in $\kappa_{\rho,GEOS5}$ below the mixed layer depths (Fig. A1b; also see Fig. 9 in (Whalen *et al.*, 2015)). The temporal variability in κ_ρ is only large near regions with active deep convection (e.g., between 40-50°N in the North Atlantic, as shown in Fig. A1b). The blue and green diamonds in Fig. 1c of (Waterhouse *et al.*, 2014) show that there are only a few microstructure profiles are within the 40-50°N band in the North Atlantic. These are all near the east coast of North America, not in regions that experience deep convection so the temporal variability in microstructure is not expected to be large enough that the disagreements in κ_ρ can be explain by temporal sampling/aliasing.

While the average $\kappa_{\rho,GEOS5}$ profile is fairly accurate, particularly below 500 meters depth (red curve in Fig. A1), $\kappa_{\rho,GMAO}$ is in much worse agreement with microstructure (green curves in Fig. A1). The large values of $\kappa_{\rho,GMAO}$ are not due to a few isolated locations. $\kappa_{\rho,GMAO}$ is too large below about 250 meters depth (solid green curve in Fig. A1). The average profile of $\kappa_{\rho,GMAO}$ is generally constant or decreases with depth, as opposed to the average profiles of $\kappa_{\rho,GEOS5}$ and microstructure,

570 which generally increase with depth. Potential reasons for the large disagreements between $\kappa_{\rho,GMAO}$ and microstructure include dynamical adjustments due to the GMAO S2S Ocean Analysis' analysis increments, inconsistencies between the model's atmosphere and ocean due to the strong relaxation to sea surface temperatures, fixed zero net water input for global sea level, and numerics such as the techniques applied to damp the waves created from assimilating some observations.

B2 Model- vs finescale parameterization-derived κ_{ρ} comparisons

575 While comparisons with microstructure reveal general agreement with the average profile of $\kappa_{\rho,GEOS5}$ —except near the surface and at deep depths—we also want to assess whether there are deficiencies in the average geographic distribution of $\kappa_{\rho,GEOS5}$ by comparing the output of GEOS-5 with the $\kappa_{\rho,W15}$ product. Comparing the $\kappa_{\rho,GEOS5}$ field with the $\kappa_{\rho,W15}$ results in better agreement than the similar comparisons between $\kappa_{\rho,GMAO}$ and $\kappa_{\rho,W15}$. For example, $\kappa_{\rho,GEOS5}$ only disagrees with $\kappa_{\rho,W15}$ by more than a factor of 3 over 36.6% of grid points with available data (Fig. A2b), while the disagreement doubles in percentage (79.1%) for $\kappa_{\rho,GMAO}$ (Fig. A2a). The errors in $\kappa_{\rho,GEOS5}$ are smaller than $\kappa_{\rho,GMAO}$. Thus, when the objective
580 of the GMAO S2S Ocean Analysis is to minimize the misfit between the model and observations of temperature, salinity, and some surface characteristics, κ_{ρ} can be better represented without any observational constraints; i.e., the GMAO S2S Ocean Analysis improves temperature and salinity misfits for the wrong reasons.

The regions with the largest disagreement between $\kappa_{\rho,GEOS5}$ and $\kappa_{\rho,W15}$ are along the equator, in the Southern Ocean, in the Labrador and Irminger Seas, and in the Gulf Stream and Kuroshio Extensions (Fig. A2b). Along the equator the values
585 of $\kappa_{\rho,GEOS5}$ tend to be larger than the observational product, but the discrepancy changes sign slightly poleward in the near-equator tropics. Inadequate resolution and parameterization of diapycnal mixing can cause too little mixing to occur in these regions as well as in the Southern Ocean and along mid-ocean ridges (MacKinnon *et al.*, 2017). The values of $\kappa_{\rho,GEOS5}$ are smaller than the observations both in regions where deep convection is prevalent and in the vicinity of the Antarctic Circumpolar Current (ACC). In the Gulf Stream Extension region, the Malvinas Current region, part of the Kuroshio Extension region, and
590 the Indian Ocean sector of the ACC above 500 meters depth, the values of $\kappa_{\rho,GEOS5}$ are too large. This is because $\kappa_{\rho,GEOS5}$ can be much increased inside the mixed layer depth, which can be deeper than 250 meters due to vertical convection. One possible source of these errors in the abyssal κ_{ρ} is the improper treatment of remote internal tide-induced mixing, discussed in (Melet *et al.*, 2016), but several other processes can impact κ_{ρ} in the upper water column. For example, the wind-driven near-inertial waves (Alford *et al.*, 2016) can be important near the surface in many locations, and internal tide breaking is
595 important near the seafloor at low latitudes in the Northern Hemisphere (Arbic *et al.*, 2004; Nycander, 2005; Melet *et al.*, 2013; MacKinnon *et al.*, 2017) and beneath the ACC, where lee wave breaking is important (Nikurashin and Ferrari, 2011; Scott *et al.*, 2011; Naveira Garabato *et al.*, 2013; Melet *et al.*, 2014; Wright *et al.*, 2014; Trossman *et al.*, 2013, 2016; Yang *et al.*, 2018). (MacKinnon *et al.*, 2017) discusses other candidates for more accurate representation of κ_{ρ} . Identifying the sources of errors in $\kappa_{\rho,GEOS5}$, particularly in the abyss, is beyond the scope of the present study. We emphasize the much greater errors
600 in $\kappa_{\rho,GMAO}$ and next examine whether the analysis increments could be one source of these larger errors (either directly or by way of altering the velocity field).

B3 Relationships between steric sea level budget terms

We now examine whether the velocity field itself changes because of the analysis increments. To do this, we show the relationship between the analysis increments and resolved advection terms in the steric sea level budget for the GMAO S2S Ocean Analysis in Fig. A3a. The Pearson correlation coefficient between the analysis increments and resolved advection terms in the steric sea level budget is about -0.3. The magnitudes of the analysis increments are determined by the temperature, salinity, and sea surface height fields, and the analysis increments and the resolved advection term in the GMAO S2S Ocean Analysis are comparable in size for both heat and salt tendencies—the largest terms in each budget in their zonal averages at most latitudes. However, previous studies have shown that analysis increments induce changes in the velocity field via dynamic adjustment (Stammer *et al.*, 2016; Pilo *et al.*, 2018). The correlation between the analysis increments and resolved advection terms shown in Fig. A3a are consistent with the findings of these previous studies. The role of the analysis increments, by a similar argument, could be extended to the introduction of physically inconsistent air-sea exchanges; we next show that these factors at least partially cause errors in $\kappa_{\rho,GMAO}$. There are distortions in temperature and salinity fields from applying analysis increments, violating conservation principles and potentially causing the model to undergo baroclinic adjustment (Stammer *et al.*, 2016). The Pearson correlation coefficients between the diapycnal diffusion terms and the analysis increment terms in the heat and salt budgets over all locations are about 0.7 (Fig. A3b), suggesting that the analysis increments are associated with errors in $\kappa_{\rho,GMAO}$. Problems with the physical consistency of air-sea exchanges—due to relaxation of sea surface temperatures and requiring net zero water input—could also contribute to the errors in $\kappa_{\rho,GMAO}$. The correlation between the surface flux and diapycnal diffusion terms in the heat and salt tendency budgets are fairly well correlated—Pearson correlation coefficient of about -0.4 (Fig. A3c), suggesting that there is an association between the surface flux errors and errors in $\kappa_{\rho,GMAO}$. Given these correlations and the way analysis increments and physical inconsistencies of air-sea exchanges are implemented in the GMAO S2S Ocean Analysis, errors in $\kappa_{\rho,GMAO}$ must be caused by analysis increments (and possibly adjustments of air-sea exchanges) rather than the other way around.

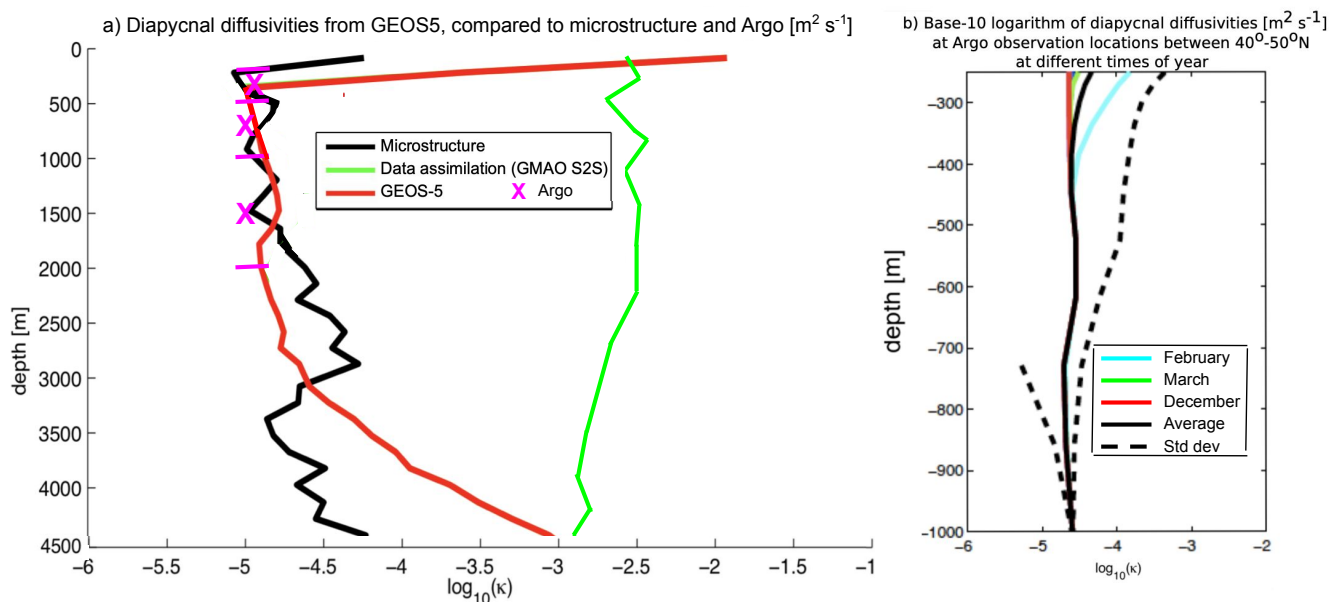

Figure A1. κ_ρ profiles (panel a) averaged over all microstructure observation locations from the 24-year-average of the free-running GEOS-5 simulation (G-CTRL - red curve). Also shown is the average of κ_ρ profiles from the 24 full-depth microstructure observations (black curve) presented in (Waterhouse *et al.*, 2014) (see their Fig. 6) and the average of κ_ρ (magenta X's bounded by horizontal lines) at each of the depth bins in the (Whalen *et al.*, 2015) product. At each location, the simulated profiles are extracted and the base-10 logarithms of the geometric averages of the observed and GEOS-5-calculated κ_ρ (units in $\text{m}^2 \text{s}^{-1}$) are shown. Also shown are (panel b) κ_ρ profiles from the free-running GEOS-5 simulation averaged over $40 - 50^\circ\text{N}$ in the North Atlantic Ocean and averaged over all January months (lighter colors), ..., and all December months (darker colors).

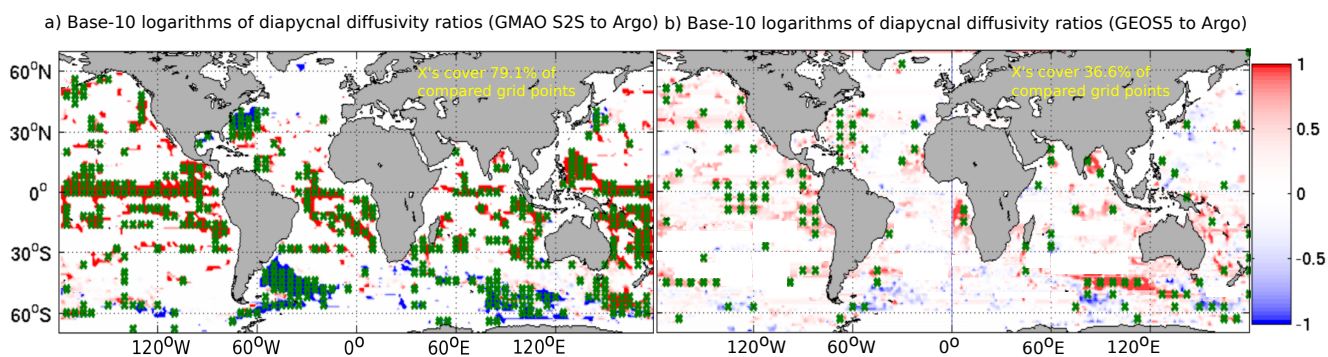

Figure A2. Shown are (a) the base-10 logarithms of the ratios of the time-averaged $\kappa_{\rho,GMAO}$ to $\kappa_{\rho,W15}$, and (b) the base-10 logarithms of the ratios of the time-averaged $\kappa_{\rho,GEOS5}$ to $\kappa_{\rho,W15}$. Each panels shows an average over 250-2000 meters depth. White areas in the ocean indicate insufficient Argo data to derive $\kappa_{\rho,W15}$. The green X's indicate regions where the disagreement between $\kappa_{\rho,GMAO}$ or $\kappa_{\rho,GEOS5}$ and $\kappa_{\rho,W15}$ is greater than a factor of 3.

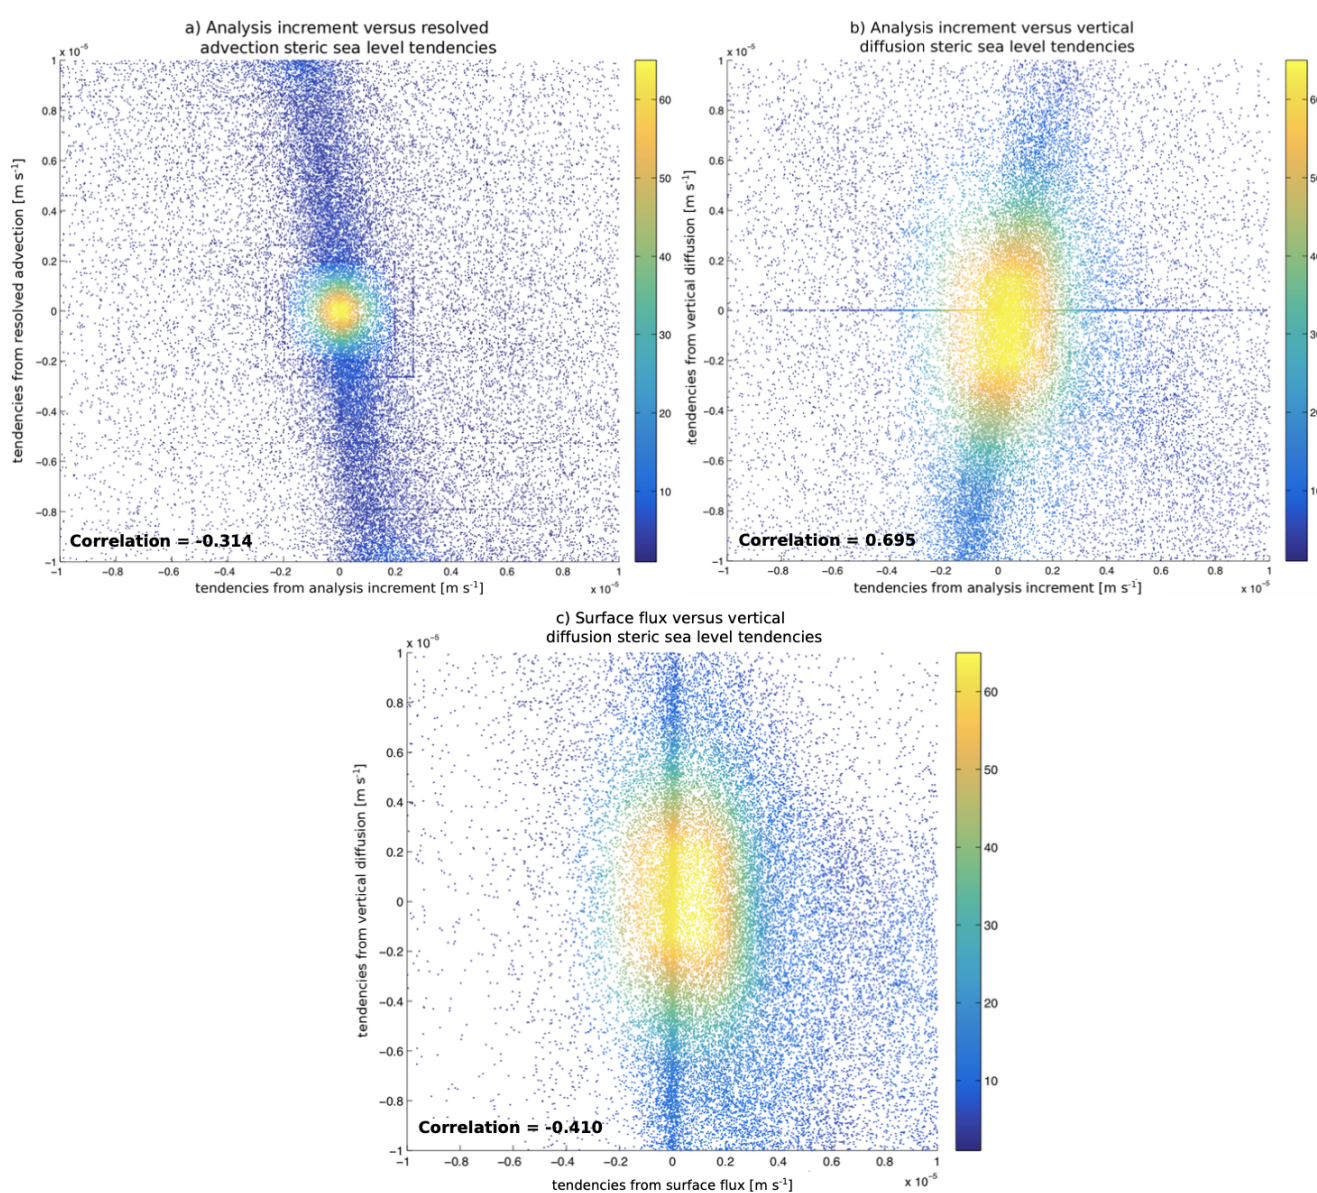

Figure A3. Scatterplots between several of the most locally dominant tendency terms in the steric sea level budget of the GMAO S2S Ocean Analysis, averaged over the entire run's time period (2012-2017): shown are (panel a) the analysis increment (abscissa) versus the resolved advection (ordinate) terms, (panel b) the analysis increment (abscissa) versus the vertical diffusion (ordinate) terms, and (panel c) the surface flux (abscissa) versus the vertical diffusion (ordinate) terms. The more yellow colors indicate a greater density of dots in the scatterplots. The more blue colors indicate a lower density of dots in the scatterplots. Also listed in each panel are the correlations between each of the comparisons.

Data availability. The data used in this study will be available through zenodo upon publication, but in the meantime, they are available at:
625 <https://www.dropbox.com/s/z4w7ihzdg3hpebr/ECCOoxygenkappa.tar.gz?dl=0> . Also, the GMAO S2S Ocean Analysis output is available at:
ftp://gmaoftp.gsfc.nasa.gov/pub/data/kovach/S2S_OceanAnalysis/ . The hydrography-derived diapycnal diffusivities from the finescale pa-
parameterization used in this study, courtesy of Eric Kunze, are available by logging in as a guest at: <ftp://ftp.nwra.com/outgoing/kunze/iwturb/>
. The microstructure data used in this study are available at: <https://microstructure.ucsd.edu/> .

Author contributions. David S. Trossman conceived of the idea, did the ECCO and GEOS-5 simulations, performed the analyses, and wrote
630 up the manuscript. Caitlin Whalen provided the Argo-derived data and helped with their use and the writing. Thomas Haine helped with the
interpretation of the results and the writing. Amy Waterhouse provided the microstructure data and helped with their use and the writing. An
Nguyen helped with the interpretation of the ECCO results and the writing. Arash Bigdeli provided help with getting the adjoint to work
with ECCO. Patrick Heimbach provided help with getting the forward MITgcm runs to get set up correctly on the TACC machines. Matthew
Mazloff helped with the interpretation of the results and the writing.

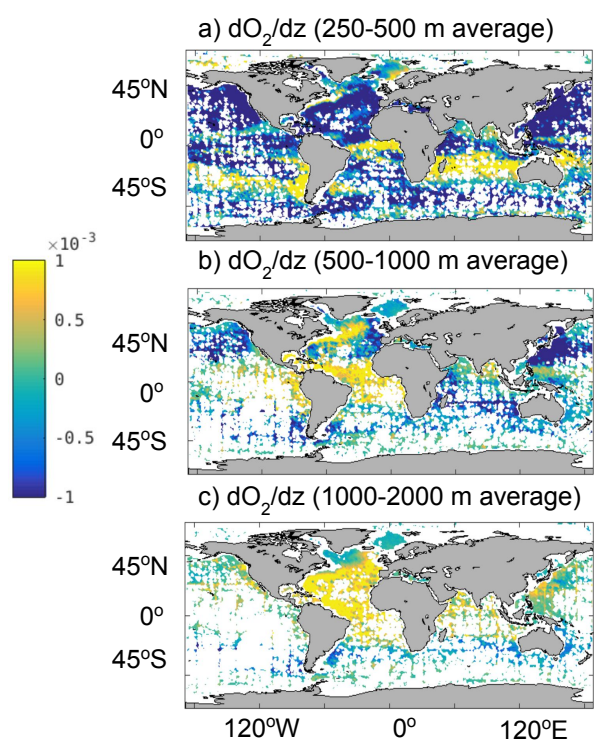

Figure 1. Shown are the vertical gradients of oxygen concentrations (units in ml/l/m) from the World Ocean Atlas (2013). Panel a shows an average over 250-500 meters depth. Panel b shows an average over 500-1000 meters depth. Panel c shows an average over 1000-2000 meters depth. White areas in the ocean indicate insufficient data.

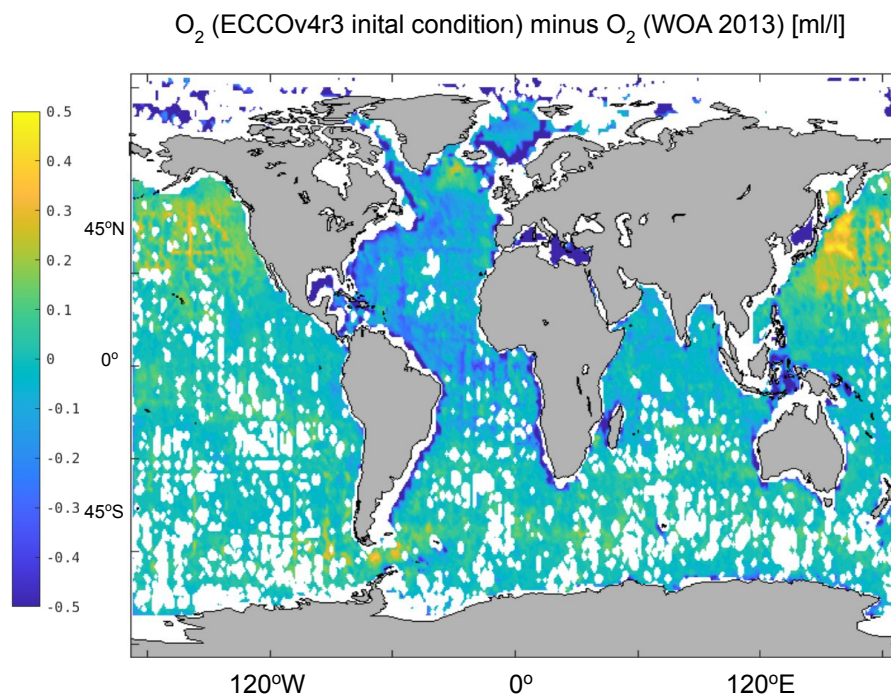

Figure 2. Shown are the average differences between the oxygen concentrations' initial conditions (units in ml/l) used for the ECCO adjoint sensitivity experiments and the observational climatologies from the World Ocean Atlas (2013) in the model's cost function. White areas in the ocean indicate insufficient data.

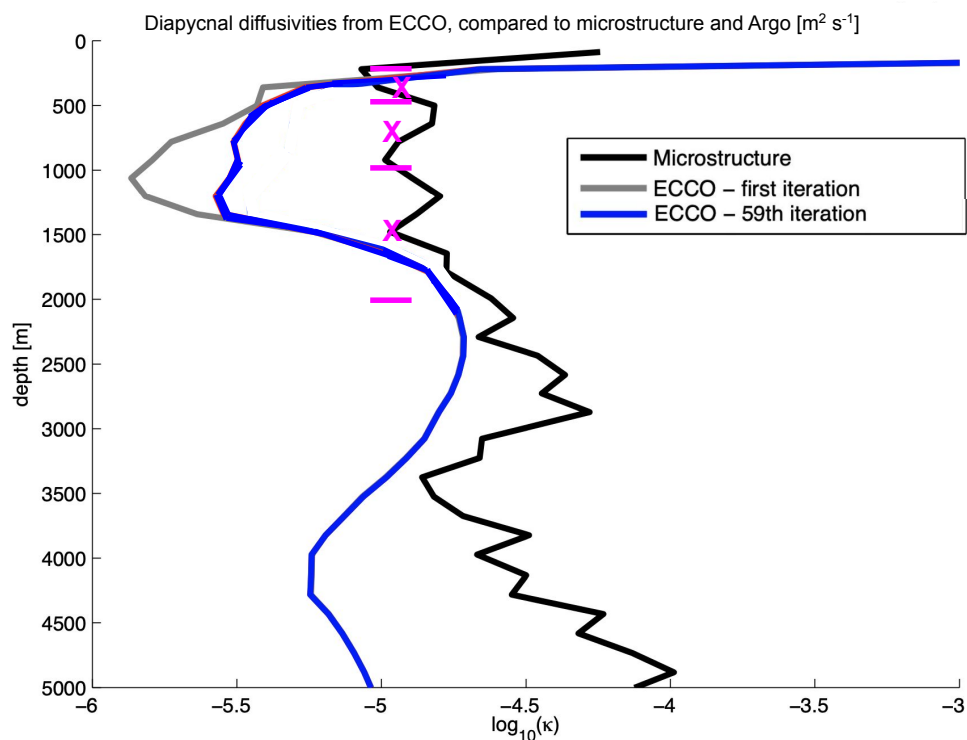

Figure 3. κ_ρ profiles averaged over all microstructure observation locations and over the length of the ECCO simulations from the first iteration of the optimization (E-CTRL₀ - grey curve), and from the (final) fifty-ninth iteration of the optimization (E-CTRL - red curve). Also shown is the average of κ_ρ profiles from the 24 full-depth microstructure observations (black curve) presented in *Waterhouse et al.* (2014) (see their Fig. 6; also see Figs. 4b,d,f of the present study) and the average of κ_ρ (magenta X's bounded by horizontal lines) at each of the depth bins in the *Whalen et al.* (2015) product. At each location, the simulated profiles are extracted and the base-10 logarithms of the geometric averages of the observed and ECCO-estimated κ_ρ (units in $\text{m}^2 \text{s}^{-1}$) are shown.

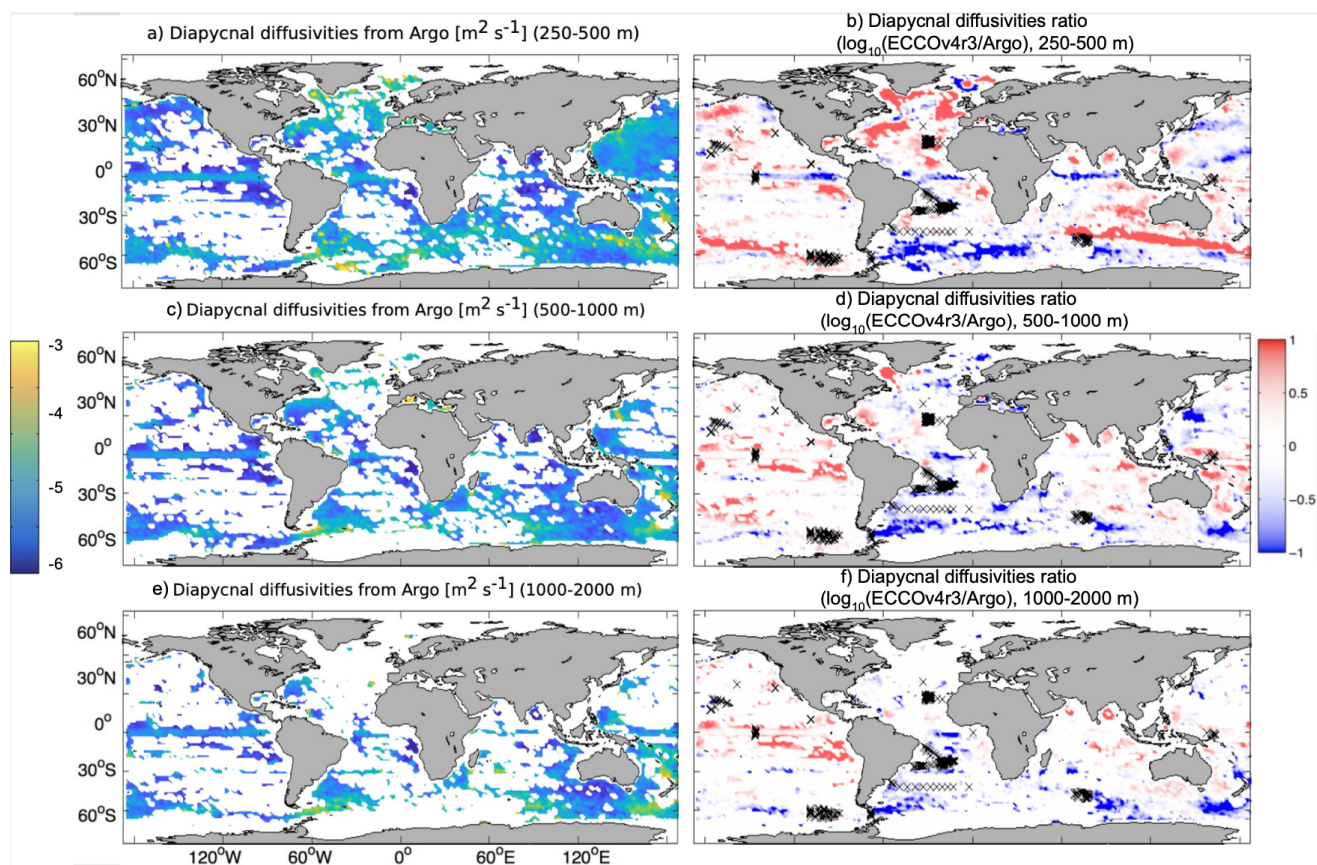

Figure 4. Shown are (a,c,e) the base-10 logarithms of $\kappa_{\rho,W15}$ (units in $\text{m}^2 \text{s}^{-1}$) and (b,d,f) the base-10 logarithms of the ratios of the time-averaged $\kappa_{\rho,ECCO}$ to $\kappa_{\rho,W15}$. Panels a-b show an average over 250-500 meters depth. Panels c-d show an average over 500-1000 meters depth. Panels e-f show an average over 1000-2000 meters depth. White areas in the ocean indicate insufficient Argo data to derive $\kappa_{\rho,W15}$. Black X's indicate locations where there are microstructure profiles used in Fig. 3.

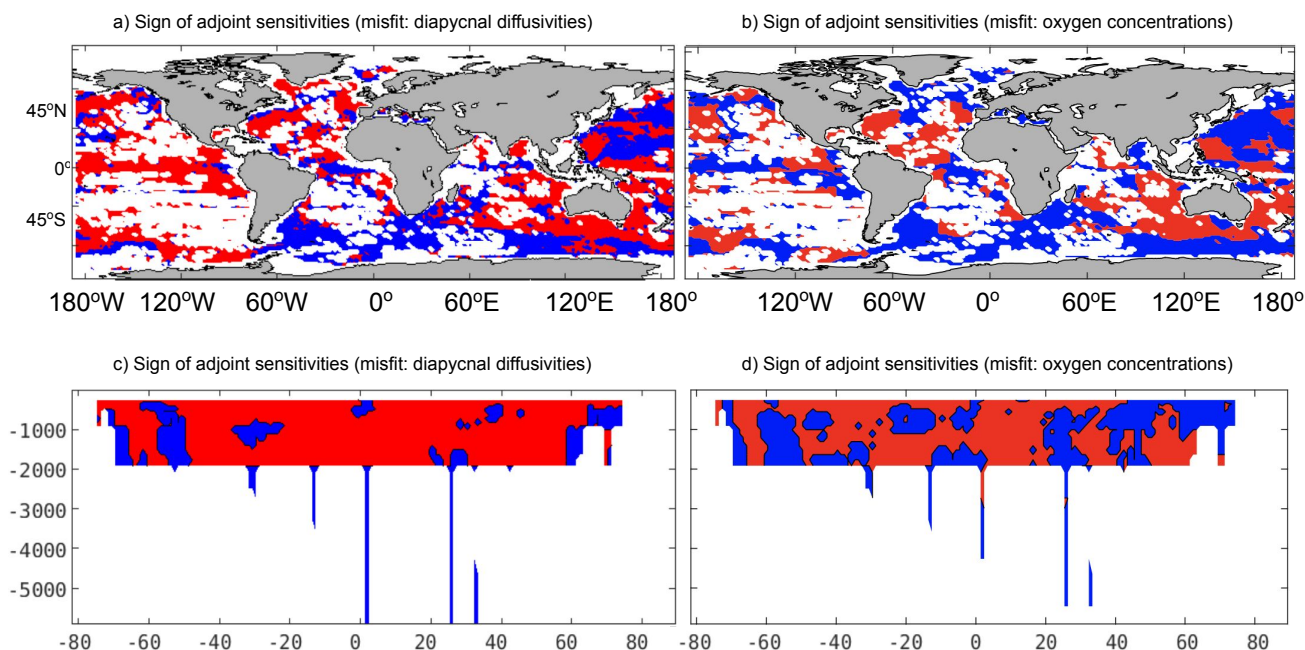

Figure 5. Adjoint sensitivity sign comparisons: Results from E_κ (panels a and c) and E_O (panels b and d) are shown for the adjoint sensitivities (units in s m^{-2}) with respect to κ_ρ : averaged over 250-2000 meters depth (panels a-b) and zonally averaged (panels c-d). The red regions indicate that the adjoint sensitivities are positive ($\partial J / \partial \kappa_\rho > 0$) and blue regions indicate negative adjoint sensitivities. $\kappa_{\rho, W15}$ and $\kappa_{\rho, K17}$ are the only quantities used in the misfit calculation of an adjoint run shown in panels a and c. The climatological oxygen concentrations from the World Ocean Atlas (2013) are the only observations used in the misfit calculation of a separate adjoint run shown in panels b and d. The adjoint sensitivities in panels a and c are computed offline (i.e., not using ECCO, but by plugging in the value the model reads in for the base-10 logarithm of κ_ρ and comparing that with the above observationally-derived base-10 logarithm of the κ_ρ products using the finescale parameterization via Eq. 2). The adjoint sensitivities in panels b and d are computed online (i.e., using ECCO, which uses the base-10 logarithm of κ_ρ as a control variable). The white regions are locations with bathymetry or insufficient observations. The adjoint sensitivities are calculated over just one year (1992).

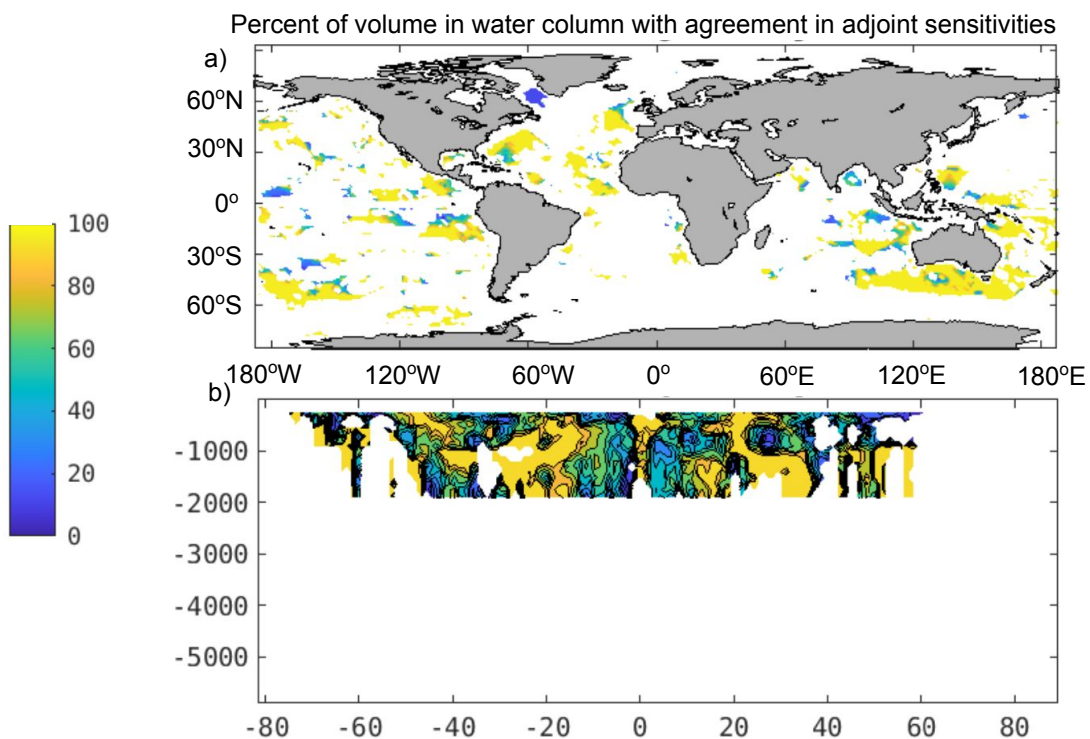

Figure 6. Shown are the percents of volume over the water column for each horizontal location (panel a) and percent of volume over all longitudes for each depth and latitude (panel b) where the sign of $\partial J/\partial \kappa_\rho$ agrees between E_κ and E_O . The white areas are locations where the disagreements between $\kappa_{\rho,ECCO}$ and $\kappa_{\rho,W15}$ supplemented with $\kappa_{\rho,K17}$ are within three times the value for the observationally-derived κ_ρ so these were excluded.

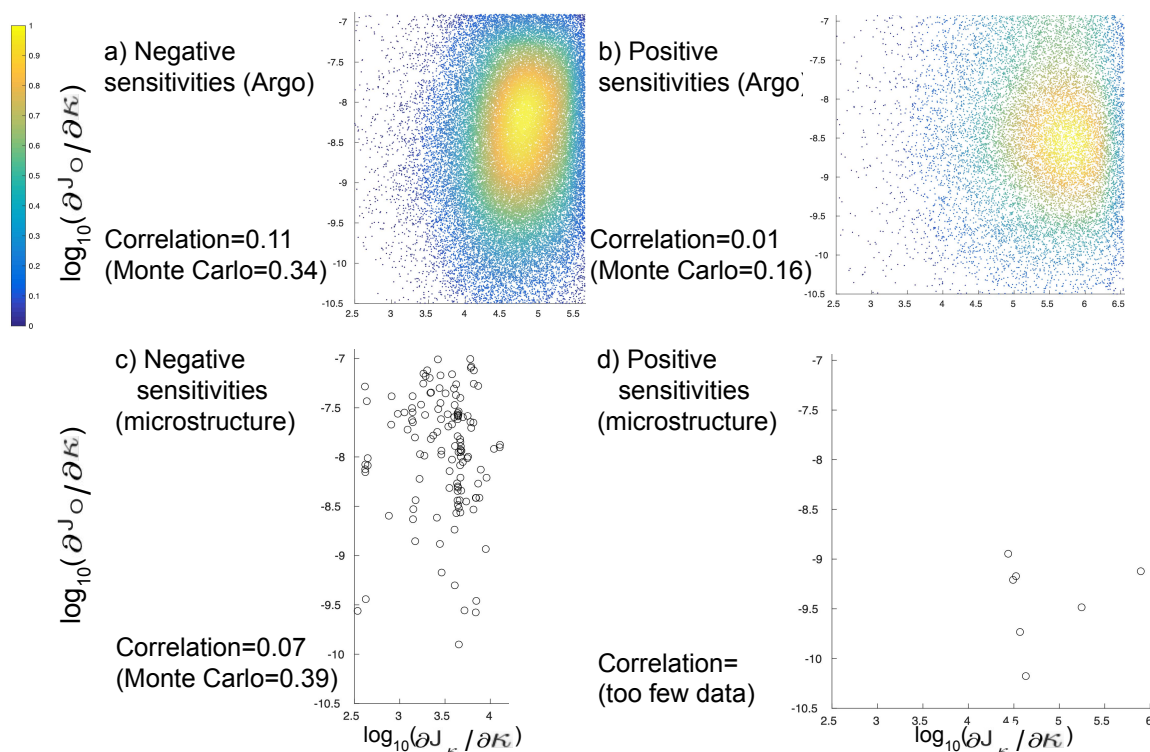

Figure 7. Shown are scatterplots between the adjoint sensitivities from E_O and E_{κ} where they are both negative (panels a and c) and where they are both positive (panels b and d), where E_{κ} has its adjoint sensitivities calculated with either Argo-derived κ_{ρ} ($\kappa_{\rho, W15}$ and $\kappa_{\rho, K17}$; panels a-b) or microstructure-inferred κ_{ρ} (panels c-d). Only the adjoint sensitivities where the differences between $\kappa_{\rho, ECCO}$ and observational κ_{ρ} products are statistically significant (greater than a factor of three) and where the differences between oxygen concentrations from ECCO and those from the World Ocean Atlas (2013) are statistically insignificant (within 2% of the latter) are included. The correlations for all of the data points shown in each panel are listed. Also listed below each panel are the maximum possible correlations from a Monte Carlo-based approach in which 10,000 random samples of κ_{ρ} within the uncertainties of the observational κ_{ρ} products are used to recompute the adjoint sensitivities for E_{κ} .

Table 1. The latitude and depth ranges of each observationally-derived product from a parameterization used in this study. The longitude range for each dataset spans ($180^{\circ}E, 180^{\circ}W$). Also listed is the time period of the observations each product is based on and the range of values in each product (to the nearest order of magnitude in units of m^2s^{-1}).

data source	range [m^2s^{-1}]	latitude range	depth range	time period
Argo ($\kappa_{\rho, W15}$)	($10^{-7}, 10^{-2}$)	($75^{\circ}S, 75^{\circ}N$)	(250,2000)	2006-2014
Ship-based CTD hydrography ($\kappa_{\rho, K17}$)	($10^{-8}, 10^{-3}$)	($77.35^{\circ}S, 78.70^{\circ}N$)	(173,6044.5)	1981-2010

Table 2. Listed are the ECCO simulations performed and analyzed in the present study as well as the observationally-derived data or measured data included in each simulation. Either observationally-derived data or measured data are included in the experiments through its misfit calculation (Eq. 1). Here, κ_{ρ} denotes an observationally-derived κ_{ρ} product from the finescale parameteration, $\epsilon = \kappa_{\rho}N^2/0.2$ indicates an observationally-derived dissipation rate (N^2 is the stratification from the World Ocean Atlas or WOA (2013)), and O_2 is the climatology of measured oxygen concentrations from WOA (2013). The misfits for the experiments with κ_{ρ} and ϵ are calculated using Eq. 2.

experiment	observationally-derived data	measured data
E-CTRL	N/A	see Section 2.2.1
E_{κ}	$\kappa_{\rho, W15}, \kappa_{\rho, K17}$	N/A
E_O	N/A	O_2 [WOA, 2013]
E_{ϵ}	$\kappa_{\rho, W15}, \kappa_{\rho, K17}$	T/S [WOA, 2013]

Table 3. The cost functions of the adjoint sensitivity ECCO runs for each data sources. Listed are the globally computed values and the number of data points used.

experiment	data source	cost function	number of data points
E_{κ}	Argo	1.91×10^{17}	5.933×10^4
E_{κ}	Ship-based CTD hydrography	2.89×10^{18}	7.3806×10^4
E_O	O_2 WOA (2013)	7.71×10^4	7.9752×10^4

Table 4. Listed are the percent volumes where the signs of the adjoint sensitivities agree between E_κ and E_O for different regions of the ocean. The boundaries of subtropical/equatorial regions are set to be at 20°N/S . The boundaries of subtropical/subpolar or subtropical/Southern Ocean regions are set to be 50°N/S . The percentages are only calculated where sufficient observations are available to derive κ_ρ and where the difference between the model-calculated and observationally-derived κ_ρ is greater than the uncertainty (i.e., three times the observationally-derived κ_ρ). In parentheses are the same, except for the dissipation rates, $\epsilon_\rho = N^2 \kappa_\rho / 0.2$, where N^2 is the stratification and 0.2 is an empirical coefficient (see, e.g., *Gregg et al. (2018)*).

region	percent of ocean volume with agreement
Global	60.8% (59.9%)
Subtropics	72.3% (72.9%)
Subtropical South Pacific	76.9% (79.2%)
Equatorial Pacific	57.9% (54.9%)
