

Validation of NEMO model against observed trend

Altimetry observed SSH trend (2005-2015; mm/yr)

Model SSH + GRD trend (2005-2015; mm/yr)

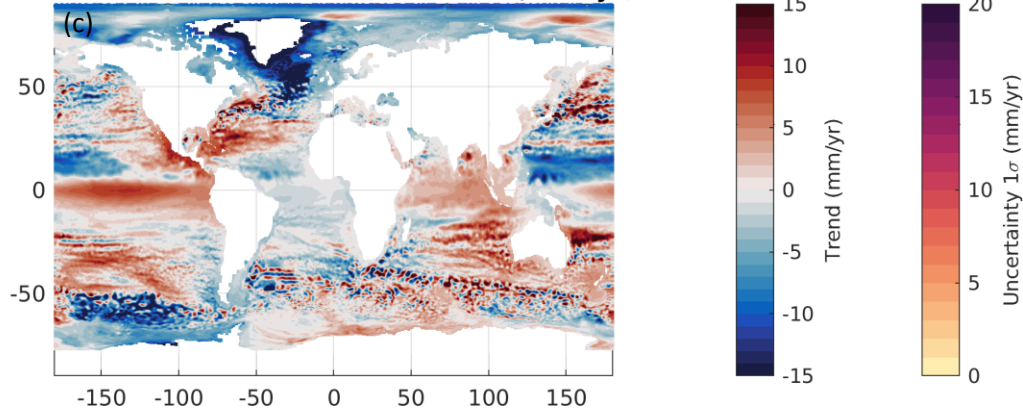

Figure S1. The linear trend from 2005—2015 inclusive for satellite altimetry observations (AVISO, 2020) the decadal trend (a) and its uncertainty assuming an auto-regressive lag-1 noise (b) and the NEMO model plus GRD geoid spatial redistribution (Frederikse et al., 2020) (c).

Climate index time series and trends

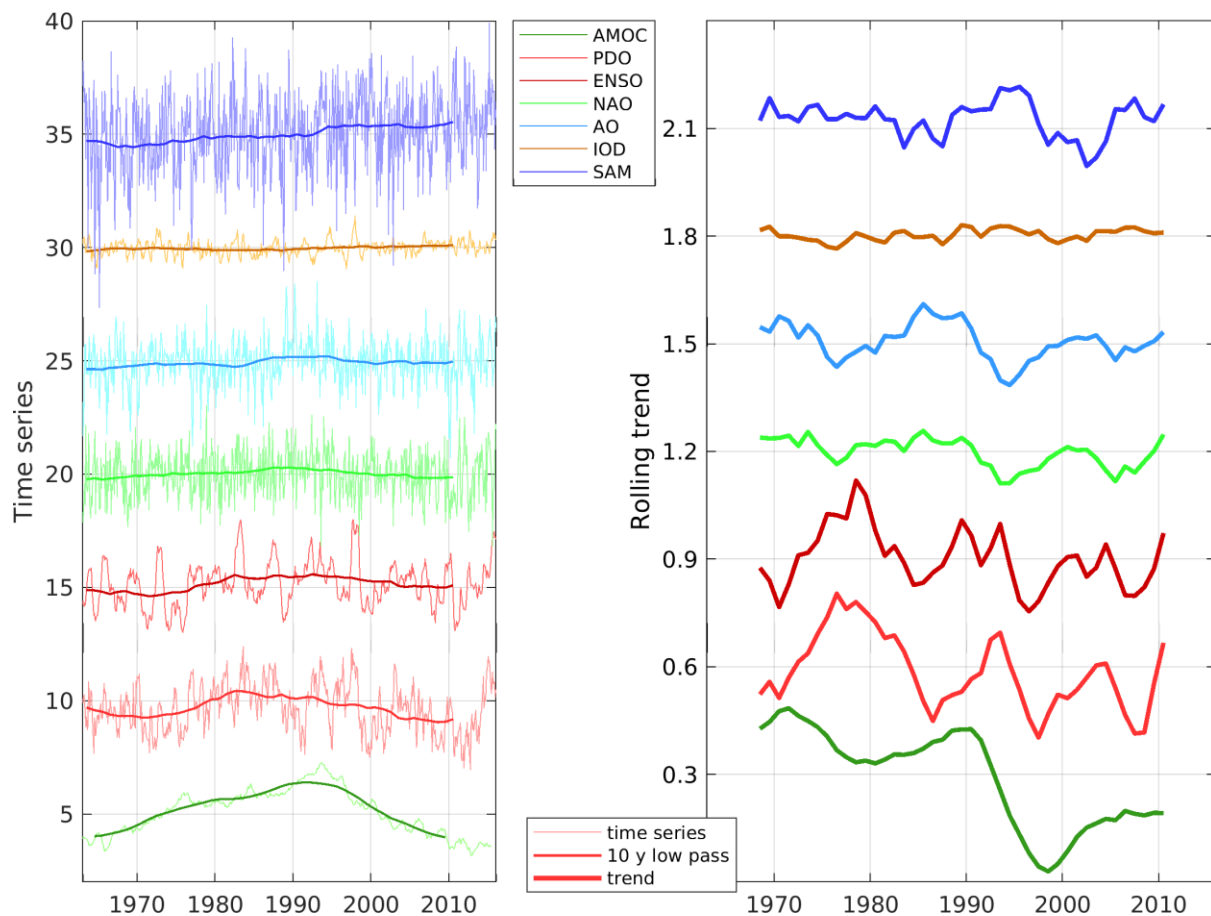

Figure S2. The time series (left) and decadal trends (right) of leading climate indices used in this study (see main text for the data citations).

Primary modes of variability in decadal trends

Taking the global, coastal ocean, the first principal component of SSH, steric sea level and manometric sea level all correlate well (statistically significant to 95 or 99%) with decadal trends in the PDO (Supplementary Information). Hence globally, the PDO dominates the decadal-scale variability of coastal sea level over other climate processes, which has been shown before (Hamlington et al., 2013; Nerem et al. 2018).

Because the PDO or ENSO decadal variability dominate the power in sea level variability, the EOF bases on a global data set are forced to be orthogonal to that mode. To investigate other drivers, we further mask the data into three oceanic basins, the Atlantic, Pacific and Indian Oceans. By focusing on each oceanic basin in turn, the dominant mode(s) from each region can be identified.

For the total SSH signal which includes GRD, the first principal component and its spatial pattern varies by basin, with the decadal rolling trends in the ENSO index having highest Pearson's correlation coefficient with PC1 in the Pacific and Indian Ocean basins but the Atlantic Ocean coastal sea level having highest correlation with the AO (Figure S3). It is notable that over the decadal timescales investigated here, the correlation of ENSO (and PDO, not shown) is diminished between

the Pacific and Indian Ocean, that the time-lag in the El Niño or La Niña type disturbance leading to a sea level disturbance through the Indonesian Throughflow is not apparent but there are peaks and troughs in the PC1 in the Indian Ocean that are not related to ENSO, particularly since 2000. It is notable that the sea-level trend pattern (EOF1) in the Atlantic Ocean is dominated by north-south dipole signals on both the east and west of the basin. An increasing (decreasing) trend in the AO can be associated with a negative (positive) sea level trend in the Baltic Sea and a positive (negative) trend in the far Eastern Mediterranean and Black Seas. An increasing (decreasing) trend in the AO can be associated with a positive (negative) trend on the US and Canadian Atlantic coasts north of Chesapeake Bay and a negative (positive) trend on the oceanward east-facing coast of The Bahamas and Greater Antilles of the Caribbean islands. Large positives on the south-east Greenland and Iceland coasts which are dominated by GRD effects (Figure S3).

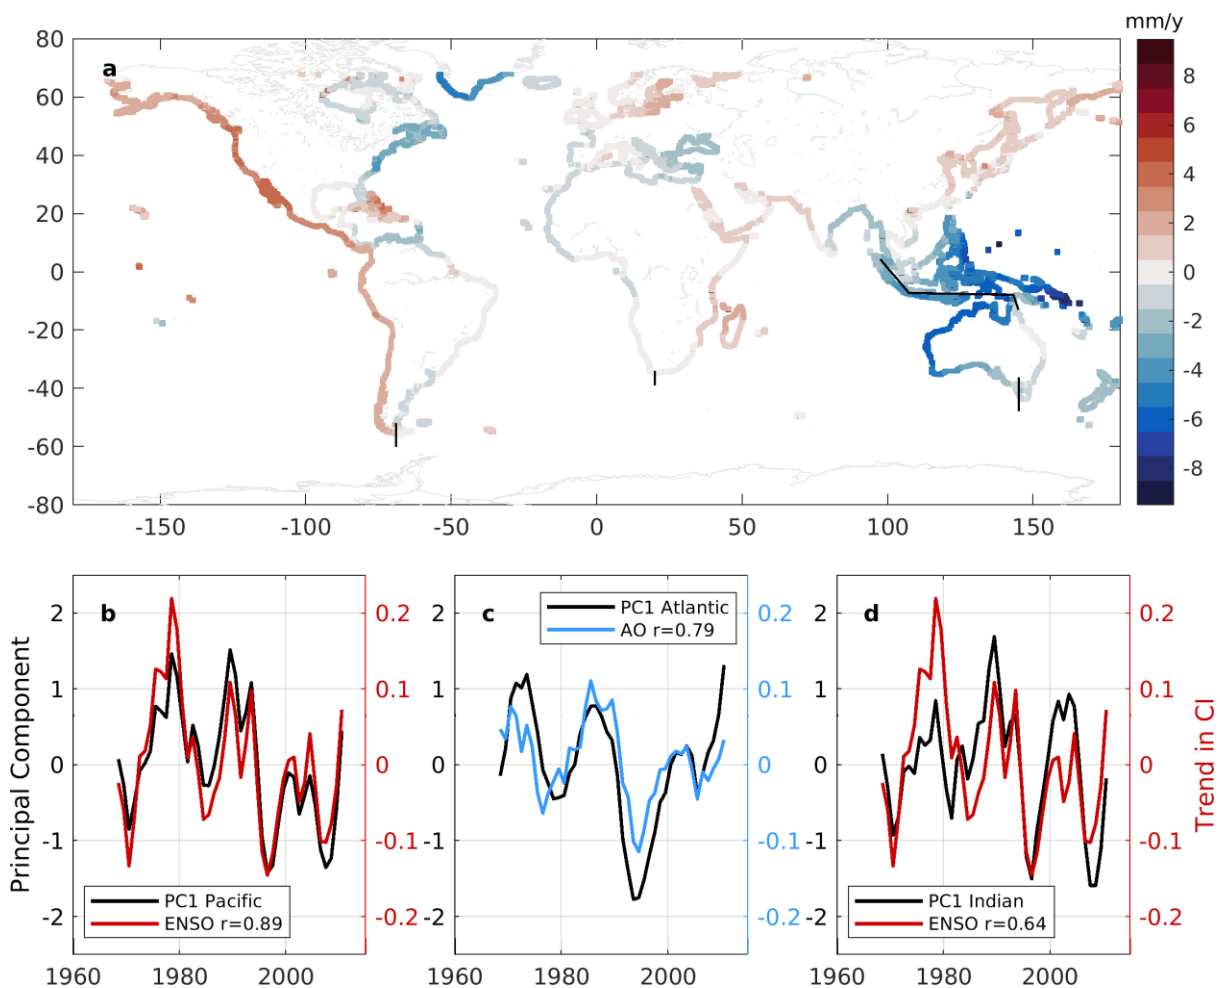

Figure S3. The spatial pattern (a) and rolling decadal trend PC1 for the Pacific (b), Atlantic (c), and Indian (d) Ocean basins shown with the climate index with highest correlation, for SSH.

The sea-level trend reconstruction presented in Figures 3 and 4 uses a linear combination of reconstructed PC modes for each basin and for each steric, manometric and GRD component, with the coefficient of the linear regression given in Table S1 for the Atlantic, Pacific and Indian basins respectively. Following which, the EOF patterns and PC time series are presented where applicable in Figures S4-S17.
